Important note: Medicine is an ever-changing science undergoing continual development. Research and clinical experience are continually expanding our knowledge, in particular our knowledge of proper treatment and drug therapy. Insofar as this book mentions any dosage or application, readers may rest assured that the authors, editors, and publishers have made every effort to ensure that such references are in accordance with **the state of knowledge at the time of production of the book.**

Nevertheless, this does not involve, imply, or express any guarantee or responsibility on the part of the publishers in respect to any dosage instructions and forms of applications stated in the book. **Every user is requested to examine carefully** the manufacturers' leaflets accompanying each drug and to check, if necessary in consultation with a physician or specialist, whether the dosage schedules mentioned therein or the contraindications stated by the manufacturers differ from the statements made in the present book. Such examination is particularly important with drugs that are either rarely used or have been newly released on the market. Every dosage schedule or every form of application used is entirely at the user's own risk and responsibility. The authors and publishers request every user to report to the publishers any discrepancies or inaccuracies noticed. If errors in this work are found after publication, errata will be posted at www.thieme.com on the product description page.

Some of the product names, patents, and registered designs referred to in this book are in fact registered trademarks or proprietary names even though specific reference to this fact is not always made in the text. Therefore, the appearance of a name without designation as proprietary is not to be construed as a representation by the publisher that it is in the public domain.

This book, including all parts thereof, is legally protected by copyright. Any use, exploitation, or commercialization outside the narrow limits set by copyright legislation without the publisher's consent is illegal and liable to prosecution. This applies in particular to photostat reproduction, copying, mimeographing or duplication of any kind, translating, preparation of microfilms, and electronic data processing and storage.

Preface

It was our hope that the first edition of this book would help improve the care of children with pediatric neurosurgical disorders and would contribute to the education of their caregivers. We have been gratified by the widespread acceptance and use of both the first edition in 1999 and the second edition in 2007, and particularly gratified by its increased use throughout the world.

In 2011, we began work on the third edition, with the same objectives as for the first edition. Organization of the book remains the same: general topics, congenital and developmental cerebral disorders, congenital and developmental spinal disorders, neoplasms, trauma, cerebrovascular disease, functional disorders, infectious disorders, and neuroanesthesia. The third edition, however, differs from the second edition in several ways. This edition includes seven chapters not included in the second edition: caring for the pediatric neurosurgical patient, cellular therapy for pediatric neurosurgical disease, conjoined twins, lipomeningoceles, skeletal syndromes, radiotherapy of brain tumors, and Moyamoya disease. The chapter on caring for the pediatric neurosurgical patient is likely to be of value daily.

We continued to invite acknowledged authorities to contribute chapters and attempted to identify individuals with balanced judgment and experience. Most of the chapters achieved that goal. Readers will note that 42 of the 82 chapters in this edition were written by different authors than the second edition—a fact that represents primarily the maturation of younger pediatric neurosurgeons into established authorities. Only 29 authors in this edition contributed to the first edition. Readers will also note that chapters in this

edition were written by authors in Europe (Richard Hayward and Dominic Thompson), the Middle East (Schlomi Constantini), and Africa (Anthony Figaji and Graham Fieggen)—a fact that acknowledges the international readership of the book, but more importantly, the international expertise about those topics.

The cover illustration—a magnetic resonance scans of a pediatric medulloblastoma and a diffuse intrinsic brainstem glioma (DIPG)—is similar to illustrations on the covers of the first two editions of the text, but includes genetic markers of those tumors that were unknown in 2007 and that have the potential to further improve the prognosis of children with medulloblastomas, and to perhaps finally improve—to at least a measurable extent—the terrible prognosis of children with DIPG.

When comparing the content of this third edition with that of the first, it is clear that pediatric neurosurgeons are able to give better care to children with many neurosurgical disorders, and far better care to those with a few disorders. It is also clear that for several classical pediatric neurosurgical disorders, such as myelomeningoceles and encephaloceles, little has improved since the first edition (other than the benefits of *in utero* closures) and to note that their incidence has steadily declined in developed countries, so that evaluation of prevention and treatment is less feasible.

Pediatric neurosurgeons, in general, are grateful for the blessing of caring for children with the disorders described on the following pages. We three editors remain hopeful that this third edition will help to further improve their care.*

* Note about the cover images: Sagittal magnetic resonance images of pediatric medulloblastoma (lower left) and diffuse intrinsic pontine glioma (DIPG, upper right). For the former tumors, recent studies have demonstrated the existence of at least four molecularly defined tumor subgroups, currently referred to as Shh, Wnt, Group C, and Group D, which have provided new insights regarding risk stratification and treatment planning. For DIPGs, which have proven resistant to conventional chemotherapy and radiotherapy approaches, recent molecular data has demonstrated frequent alterations in histone modification genes and *PDGFRA*. Time will tell whether these insights will translate into improvements in response and survival for children with these challenging tumors.

1 The History of Pediatric Neurosurgery

R. Michael Scott

1.1 Introduction

The beginning of the subspecialty of pediatric neurosurgery is perhaps best documented in a letter, currently in the possession of the Chief of Pediatric Neurosurgery at the Boston Children's Hospital, written by Harvey Cushing in 1929 to a woman requesting care for her child with a probable brain tumor: "the right thing is to have you take him to see Dr. [Franc] Ingraham at the Children's Hospital, and to abide unequivocally by what he says." Over the next 30 years, neurosurgeons around the world began to devote major parts of their practice to the care of infants and children with neurosurgical disorders, and by the early 1950s, dedicated pediatric neurosurgical services were being established in the world's major cities, including Boston, Buenos Aires, Chicago, London, Paris, Philadelphia, and Toronto, to name just a few. A major reason for the development of these services was the increasing prominence of prestigious children's hospitals staffed by committed pediatric subspecialists in all areas of medicine and surgery, who were founding world-renowned services in their own specialties. It was only natural that pediatric neurosurgery would come into its own, driven by similarly committed neurosurgeons and institutions influenced by dedicated pediatricians, subspecialists, and hospital administrators, who wanted only the best-trained neurosurgical specialists to care for their patients. As Robin Humphreys pointed out in the earlier edition of this chapter, however, many neurosurgeons who specialized in the care of pediatric patients continued to have simultaneous adult practices through the 1960s and 1970s. At the time of this writing (2012), however, there are now several hundred neurosurgeons in the United States and Canada whose practices are limited to pediatric patients, and who practice exclusively in pediatric hospitals. How did this change come about?

One of the major influences on the development of our subspecialty was the publication of influential textbooks that outlined the presenting signs and symptoms of pediatric neurosurgical disorders, their diagnosis, and their surgical management. The anatomy and treatment of many congenital anomalies were difficult to understand, given the limitations of imaging before the development of computed tomography (in the 1970s) and magnetic resonance imaging (in the 1980s), and the rarity of many of these conditions; an experienced pediatric surgeon's delineations of these conditions via a text was often the only way of advancing knowledge in the field of neurosurgery. The medical publisher Charles C Thomas published many short, themed monographs on conditions like medulloblastoma and spina bifida, and many pediatric case series were published in our journals, particularly the *Journal of Neurosurgery*, but it was not until the pivotal *Neurosurgery of Infancy and Childhood*,¹ by Franc D. Ingraham and Donald D. Matson, published in 1954, that any such compendium was available for the interested neurosurgeon or resident. The second edition, now authored

solely by Matson, was published in 1969,² and it became the authoritative pediatric neurosurgical text for many of us in training or in practice during that era; many of Matson's diagnostic aphorisms remain relevant even today. The text remains a fascinating window into the treatment strategies of the pediatric neurosurgeon practicing in the middle of the 20th century. Other texts were published over the next two decades, but as pointed out by Robin Humphreys, quoting the comments of Kenneth Till, it was not until pediatric neurosurgeons "began to discover one another"^{3,4} and to discuss mutual interests that this special area of neurosurgery began to flourish and subspecialty societies began to form to encourage the exchange of ideas and promote better care for the pediatric neurosurgical patient.

In the first edition of this chapter, Dr. Humphreys canvassed pediatric neurosurgeons at some of the oldest and most established pediatric neurosurgical centers in the world to record their histories for posterity, and I have quoted liberally from his initial chapter depictions in the sections that follow.

1.2 Program Development and Institutional Histories

1.2.1 Australia (E. A. Lewis, MD and D Simpson, MD, Written Communications to Dr. Humphreys, October 2004)

The development of pediatric neurosurgery from its general neurosurgery roots is well illustrated by its evolution in Australia. General surgery arrived with the first fleet in 1788, but it was more than 100 years before the first successful adult neurosurgical cases were undertaken. The grandfathers of pediatric neurosurgery in Australia, like those in many other countries, had obtained their initial experience in other disciplines. T. Y. Nelson, a general pediatric surgeon, and his pupil, Marcel Sofer Schreiber, were perhaps the earliest practitioners of children's neurosurgery in Sydney. Reginald Hooper, who in the late 1950s was appointed to the Royal Children's Hospital, took the lead in Melbourne. Donald Simpson had been working in Adelaide since 1949; by 1956, he had established a relationship with the Adelaide Children's Hospital.

The Australian neurosurgical community also felt Donald Matson's influence when Matson visited that country in 1966, by which time freestanding children's hospitals located in the country's capital cities had been established. Then, as now, the challenge was the provision of "high-quality service over the tyranny of distance" (E. A. Lewis, MD, written communication to Dr. Humphreys, October 2004). Today, there are neurosurgeons specializing in pediatric neurosurgery throughout Australia and New Zealand.

1.2.2 Boston, Massachusetts—Boston Children’s Hospital

“If anyone can lay claim to be the father of pediatric neurosurgery, it would be Franc Ingraham.”⁵ Born in 1898, Ingraham entered Harvard Medical School in 1921 and received his medical degree 4 years later. He then spent 3 years with Harvey Cushing, 1 year in surgical research at Johns Hopkins, and an additional year working with Sir Charles Sherrington in the physiology laboratories at Oxford. Returning to Boston from England in 1929, Ingraham, with his extensive clinical and investigative background, focused on the rapidly expanding area of neurologic surgery for children at Cushing’s request.⁶ As noted earlier in this chapter, he started a pediatric neurosurgical service at Boston Children’s Hospital that to the author’s knowledge was the first of its kind. Generations of pediatric neurosurgeons in America and throughout the world were the benefactors of either his tutelage or that of his pupil, co-worker, and successor, Donald Matson. Over 40 neurosurgeons came to Boston Children’s Hospital to spend extended periods of time learning this new subspecialty, and many of them became chairpersons of their own departments or directors of their own pediatric neurosurgical services in academic institutions throughout North America and the world. Ingraham and his colleagues described the diagnosis and treatment of such clinical entities as subdural hematoma during the first 2 years of life,⁷ subdural effusions complicating bacterial meningitis in infancy,⁸ premature closure of cranial sutures,⁹ diastematomyelia,¹⁰ persistent dermal sinus tracts, and other variations of congenital spina bifida,¹¹ as well as the classification and treatment of hydrocephalus.¹¹ Ten years before his 1954 text with Matson, Ingraham had published *Spina Bifida and Cranium Bifidum*.¹² Matson and Ingraham’s collaboration sadly ended with Ingraham’s death in 1965 and Matson’s demise 4 years later of Jakob-Creutzfeldt disease.

1.2.3 Buenos Aires, Argentina (G. N. Zuccaro, MD, Written Communication, January 2005)

Raul Carrea was perhaps the first dedicated pediatric neurosurgeon in Argentina, beginning neurologic research when he was a student. In the mid 1940s, he worked with Pio del Rio Ortega. Shortly afterward, he continued his training as a Commonwealth Fund fellow in New York at Columbia University, where he worked both in neurophysiology research and in neurosurgery. Following his return to Buenos Aires, Carrea developed his neurosurgical career at the Cancer Institute Angel H. Roffo and at the Ricardo Gutierrez Children’s Hospital. Although this hospital had been founded in 1875, there was no designated neurosurgeon; general surgeons operated on the sporadic neurosurgical cases. At that institution, Carrea in 1956 created the first Department of Pediatric Neurosurgery, with its own special ward, an associated neuroradiology facility, and operating rooms. It was the first such department in Argentina. Subsequently, he created the first residency program in neurosurgery

at the Children’s Hospital based on his belief in the need for specialized training.

Carrea’s interest in the treatment of hydrocephalus resulted in the imaginative strategy of deviating obstructed cerebrospinal fluid to the mastoid air cells, thereby saving the lives of many children at a time when shunt systems did not exist. Eventually, he designed his own shunting system, but the cost restricted its accessibility to families with means. The budget restrictions at the Children’s Hospital prompted Carrea to organize a group of parents and wealthy friends to create the Foundation for the Fight against Neurological Diseases in Childhood (FLENI). The foundation flourished under his leadership, and his department of neurosurgery became a state-of-the-art center that still has an international reputation in the field of neurologic diseases.

1.2.4 Cape Town, South Africa—Red Cross War Memorial Children’s Hospital

The Department of Neurosurgery in Cape Town was established in 1946 by Hermann de Villiers Hammann, a South African trained in Germany.^{13,14} As a rule, children were operated on by general neurosurgeons until 1970, when Professor J. C. (Kay) de Villiers was appointed as the first full-time academic neurosurgical head in Cape Town. He quickly recognized that there was a need to establish pediatric neurosurgery as a subspecialty; this decision was facilitated by the fact that Cape Town had the only freestanding pediatric hospital in South Africa. The Red Cross War Memorial Children’s Hospital had been established after the Second World War with contributions from the citizens of Cape Town, given in memory of those fallen. De Villiers developed a combined spinal dysraphism clinic, which he ran assisted by personnel from the orthopedic and urology departments. In the years that followed, the first full-time academic pediatric neurosurgical post was created at the Children’s Hospital, and the hospital became the referral center for most of southern Africa.

1.2.5 Chicago, Illinois—Children’s Memorial Hospital (D. G. McLone, MD, Written Communication to Dr. Humphreys, June 2004)

Neurosurgery was established at Children’s Memorial Hospital in 1950 by Luis Amador, who must have been influenced by the presence of Paul Bucy and Percival Bailey at Northwestern University. Amador, described as a true academic and technically skilled surgeon, held only a part-time appointment at Children’s Memorial Hospital, which was typical for that era. During that decade, he accepted international trainees, such as Kenneth Till and Sanat Bhagwati, for additional experience in pediatric neurosurgery; this training opportunity for neurosurgeons from around the world was to become a consistent feature of the pediatric neurosurgical service at Children’s Memorial Hospital during the years that followed. Bhagwati, training

with both Till and Raimondi, went on to spearhead the development of pediatric neurosurgery in India, where over 150 neurosurgeons now devote most of their practice to the care of pediatric patients.¹⁵

Meanwhile, Anthony Raimondi, born and raised in Chicago but schooled in medicine at the University of Rome, had completed his neurosurgical residency with Joe Evans at the University of Chicago.¹⁶ During this time, Raimondi had an opportunity to study pediatric neurology under Douglas Buchanan. This experience doubtlessly contributed to his decision to dedicate his life to pediatric neurosurgery. In what would now be considered a fellowship, Raimondi worked with Amador at Children's Memorial Hospital. In 1963, when he was 34 years old, Raimondi went across town to the Cook County Hospital. Although his responsibility was primarily the care of adult patients, he was still absorbed by the surgical disorders that affect a child's nervous system. He was intrigued by the potential of cerebrospinal fluid shunt systems as well as the utility of cerebral angiography as a diagnostic tool in children.

In 1968, Bucy prevailed upon Raimondi to return to Children's Memorial Hospital as Chairman of Pediatric Neurosurgery, and Raimondi subsequently became Professor and Chairman of Neurosurgery at Northwestern University. As an educator, Raimondi did not disappoint the university. As a testament to Raimondi's passion for the training of many young neurosurgeons (at least 25 of whom were from Japan alone) and the promotion of continuing education programs in pediatric neurosurgery, five of his former students have served as presidents of the International Society of Pediatric Neurosurgery.

1.2.6 Edinburgh, Scotland—Royal Hospital for Sick Children (A. J. W. Steers, MD, Written Communication to Dr. Humphreys, July 2004)

Not long after he qualified as a doctor in 1919, Norman McOmish Dott received a Rockefeller Fellowship to study at Peter Bent Brigham Hospital, where he was appointed as a junior associate in surgery to Harvey Cushing.¹⁷ "In one of his letters, Dott describes a case of intussusception, and tells Cushing that the techniques that he has learnt from him in Boston have helped him even in his pediatric general surgical practice."¹⁸ By 1925, Dott was an established pediatric surgeon holding an appointment as an honorary surgeon at the Royal Hospital for Sick Children in Edinburgh. He subsequently published articles on hydrocephalus and other pediatric surgical topics, such as anomalies of intestinal rotation. In Edinburgh, Dott was determined "to set up not only his own department of surgical neurology, but also a similar centre of training and influence where precepts he had just learnt could be instilled in young surgeons." That he achieved his aims is well known, yet even "though his credentials were unimpeachable, he never labelled himself 'a paediatric neurosurgeon'."¹⁷ Nevertheless, in 1955 during a major address, he claimed, "Such success as I have had I owe, very largely, to my little patients. I would commend paediatric surgery, as the first training ground in surgical technique and management."¹⁸ Dott

retired in 1962; John F. Shaw, one of his protégés, who had visited Matson in Boston and Bruce Hendrick in Toronto, was "encouraged to take on the paediatric neurosurgical work."

1.2.7 London, England—Hospital for Sick Children

In 1945, Kenneth Till made a favorable impression upon Mr. Wylie McKissock while serving an appointment at Atkinson Morley's Hospital in Wimbledon, England.¹⁹ Till was put "in charge of the smallest ward, the children's ward." As has happened to so many before and after him, a single case experience with a small child suffering from an infected cerebellar dermoid cyst promoted in Till "a decided impetus" to pursue pediatric neurosurgery. Upon completion of his training and his demonstrated preference for working with children, Till nevertheless encountered a negative attitude toward his pursuit of the subspecialty. At the time, the Hospital for Sick Children in London sent patients with neurosurgical conditions to Atkinson Morley's Hospital 15 miles away, where there were no pediatric facilities. Yet, the Hospital for Sick Children was proud of its ability to manage most pediatric conditions and was already a flourishing tertiary referral center. Wylie McKissock, who was on the staff of the Hospital for Sick Children but never actually operated there, was asked to set up a neurosurgical department in that facility; he was apparently not much in favor of the request and demanded resources far beyond the means of most National Health System hospitals. Unexpectedly, his demands were met, and Kevin Till became part of the new team.¹⁹

In the early days of his pediatric practice, Till acknowledged the influence of Ingraham and Matson on his own practice, thereby extending the Boston influence to the United Kingdom. Having spent time in Boston as well as at Children's Memorial Hospital in Chicago, Till was delighted to have Matson journey to London to assist him with the surgical removal of a child's craniopharyngioma.

1.2.8 Mexico City, Mexico—Hospital Infantil de Mexico (F. Rueda-Franco, MD, Written Communication to Dr. Humphreys, May 2004)

The president of Mexico inaugurated the Hospital Infantil de Mexico (Children's Hospital of Mexico) on April 30, 1943. Clemente Robles was the appointed neurosurgeon; however, he acted only as a consultant because there was no special ward for neurologic surgery. As was typical for the time, Professor Robles, a gifted surgeon trained in Europe, operated on the abdomen and within the chest (performing open-heart surgery) in addition to undertaking neurosurgical procedures.

Miguel Ramos-Murguía succeeded Professor Robles in 1953. Returning from the United States, where he trained at the Neurological Institute of New York under J. Lawrence Pool, Ramos-Murguía founded the neurosurgical service at the Children's Hospital of México, the first pediatric neurosurgical unit in the country.

1.2.9 Pacific Rim—Japan, Korea, and Taiwan

Pediatric neurosurgery in the Pacific Rim countries was influenced by North American centers, in particular by Children's Memorial Hospital in Chicago, as noted above. Countries like Japan, Korea, mainland China, and Taiwan also had their neurosurgical giants in the 1930s and 1940s, who provided children with surgical care in situations similar to those existing in Europe and North America at that time.

Yutaka Maki credits Raimondi with initially planting “the first seedling, namely [Satoshi] Matsumoto, in Japan followed by others of his residents, one after another forming a new plantation that would grow into a forest of pediatric neurosurgery.”¹⁹ Matsumoto returned to Japan in 1971, having completed his full residency and research in Bonn, Germany, and “devoted himself to the establishment of [the] Japanese Society for Pediatric Neurosurgery (1973).” Subsequently, other Japanese surgeons interested in pediatric neurosurgery were to travel to Boston, London, Marseille, and Toronto to hone their skills.

Neurosurgery in Korea also began as an offshoot of general surgery (J.-U. Choi, MD, written communication, June 2004). Ventriculo-subgaleal and Torkildsen shunt procedures are listed in the logs of Severance Hospital, Seoul, in the early 1940s. Hun Jae Lee, another pioneer of Korean neurosurgery, who completed his residency training at the University of Michigan under Edgar Kahn in 1957, was allegedly the first to undertake a procedure using the Holter valve in Korea in the late 1960s. However, it is Yoon-Sun Hahn who is credited with initiating pediatric neurosurgery in Korea, following his return home from Children's Memorial Hospital in Chicago.

Subspecialty organizational developments are now apparent in mainland China (where a pediatric neurosurgical society has been formed), as well as in Taiwan (T.-T. Wong, MD, written communication, May 2004). To this day, there continues to be an exchange of interested young men and women who travel worldwide from the Pacific Rim countries in search of supplementary experience in children's neurosurgery.

1.2.10 Paris, France—Hôpital des Enfants Malades

Jacques Rougerie, regarded as the pioneer of pediatric neurosurgery in France in the 1950s, catalyzed discussions about the “individualization” of this discipline with colleagues in Paris.²⁰ His untimely death stalled the deliberations until the mid 1960s, when Jean-François Hirsch “tried to speed up the process.” Hirsch noted that several core issues were examined, the most key being whether children's neurosurgery was to be performed in a pediatric hospital or linked to an adult neurosurgical department in a general hospital. Hirsch clearly preferred the former arrangement. Nevertheless, for Hirsch the process was slow and arduous. In 1970, the first independent service of pediatric neurosurgery in France was established at Hôpital des Enfants Malades in Paris. However, Hirsch claims that it took many meetings to gain an identity for the unit; resources

increased slowly, as did the major alterations to the facilities. In his opinion, it took two decades before the service was functioning at an optimal level.

1.2.11 Philadelphia, Pennsylvania—Children's Hospital of Philadelphia (L. N. Sutton, MD, Written Communication to Dr. Humphreys, January 2004)

The obstacles that surgeons encountered in children's hospitals are illustrated well by the experiences in Philadelphia in the early 1950s. C. Everett Koop (later to become surgeon general of the United States) was instructed by the Chairman of Surgery at the University of Pennsylvania School of Medicine to create a department of pediatric surgery at The Children's Hospital of Philadelphia. Reportedly, Joseph Stokes, then a professor of pediatrics at The Children's Hospital, was reluctant to set up a separate surgical division. Nevertheless, Koop was successful in developing one of the first and largest departments of pediatric surgery in the country. Shortly thereafter, he asked Eugene Spitz to become surgeon in charge of the neurosurgical service, the second such unit dedicated to children in the United States. In 1957, Luis Schut, a resident in neurosurgery at the University of Pennsylvania School of Medicine, was asked to assist Spitz at The Children's Hospital. He then worked with Spitz first as a fellow and later on as an associate. Upon his return in 1962 from Great Britain, where he had obtained experience as a senior registrar, Schut joined Spitz as one of his junior staff members. Schut became known as an important teacher and mentor for scores of residents and fellows at the University of Pennsylvania, many of whom are in the full-time practice of pediatric neurosurgery throughout the world.

1.2.12 Toronto, Canada—The Hospital for Sick Children

Nine years after Kenneth G. McKenzie launched Canadian neurosurgery at the Toronto General Hospital, William S. Keith was appointed in 1933 to the Hospital for Sick Children. In due course, Keith took on the care of children requiring neurosurgical treatment. In preparation, he studied at the University of Chicago and afterward took a clerkship in the neurology service at the National Hospital in London. Upon his return to Toronto, Keith was expected to be equally facile in general and orthopedic surgery, as well as neurosurgery. Keith was not a favorite of the powerful chief of pediatrics, who presided over the hospital as a stern father would over his family. They argued over which patients Keith would operate on and even where he was to park his car.

In 1952, E. Bruce Hendrick, a resident in the postgraduate training program in neurologic surgery at the University of Toronto, was informed that he was being “given the opportunity of a lifetime” to take a year of training at Boston Children's Hospital to study pediatric neurosurgery under Ingraham and Matson. Years later, Hendrick confessed that at the

time “I knew very little about Ingraham or Matson and nothing about pediatrics.”²¹ However, he had observed that despite Bill Keith’s presence, only a few pediatric neurosurgical procedures were being performed at Toronto’s Hospital for Sick Children. As elsewhere, a significant number of children with brain and spinal cord tumors were transferred to the Toronto adult hospital for surgery and then returned to the pediatric service for aftercare and convalescence. Children with head injuries were admitted to the hospital under the care of the general surgeons, who also operated on infants with myelomeningocele. Hendrick thus concluded that pediatric neurosurgery was a minor part of the Toronto neurosurgical scene, as elsewhere. All of that changed after Hendrick returned to Toronto in 1954 to pursue what he described as his “eccentric interests at the Children’s” and to become Canada’s first full-time pediatric neurosurgeon. Hendrick’s later trainees and associates, Robin Humphreys and Harold Hoffman, established a training program in pediatric neurosurgery that became renowned for its excellence and international influence.

1.3 Establishing the Identity of Pediatric Neurosurgery

Surgeons like those just described, who were practicing pediatric neurosurgery around the world, took steps by the mid 1960s to assign identity to their subspecialty. Hirsch reflected that “three pre-requisites [were] to be fulfilled before a specialty can be recognized as such:

1. individualization of a specific body of knowledge;
2. recognition of the specific nature of this knowledge by people who will create the means necessary to the practice and development of the specialty;
3. conferring an official status on it by way of political decisions and the creation of dedicated learned societies.”²⁰

Pediatric neurosurgeons became more and more interested in obtaining new and innovative information about their discipline, and they wanted to participate in forums where they could learn from the experiences of senior or more experienced colleagues.

Specialty organizations were gradually created. The European Society for Pediatric Neurosurgery (ESPN) was founded at the first European Congress of Pediatric Neurosurgery, held in Vienna in 1967; Donald Matson was the guest of honor. In 1972, what was identified then as the American Association of Neurological Surgeons, Pediatric Section, met for the first time in Cincinnati, Ohio; the pediatric section was the first of the subspecialty sections formed within the association. The American Society of Pediatric Neurosurgeons (ASPEN) was formed in 1978. Similar professional organizations have arisen in Japan (1973), Mexico (1999), and most recently Australia (2002). Each is governed by its own bylaws, and each has defined qualifications for membership. The birth of these professional societies reflected the increasing attention to children’s neurosurgery that was taking place around the world and the bonding of their members, who were seeking to develop their skills exclusively for the benefit of children.

In the autumn of 1971, Jacques Rougerie hosted a meeting in Paris, in part to “determine whether this was an opportune time to convert [the ESPN] to an international society.”¹⁶ Some of the individuals identified subsequently as founding members of the International Society for Pediatric Neurosurgery attended that meeting; however, it was concluded that the ESPN would continue as originally intended. Nevertheless, the concept of an international organization had gained momentum, with the result that the International Society for Pediatric Neurosurgery (ISPN) was created in 1972. Its first meeting was hosted by Satoshi Matsumoto in Tokyo in 1973; it was presided over by Jacques Rougerie, President; Anthony Raimondi, Secretary; and Bruce Hendrick, Treasurer.

In 1973, during a pediatric neuroradiology symposium held in Chicago, Illinois, Carrea and Raimondi entered into a discussion about clothing. Raimondi proudly displayed his Colombian *ruana* (or poncho), which was made of plaid wool with a slit for the head. Not to be outdone, Carrea defended the elegant and delicate Argentinean poncho and promised to give one to Raimondi. He did so a year later, and Raimondi protectively tucked it away for “future use.”²² At the request of Raimondi, on Carrea’s death, the poncho became the symbolic vestment of each new president of the ISPN at future meetings. The poncho’s skirts have been embroidered with the names of all the presidents of the society from Jacques Rougerie onward, and it has been passed annually from one president to the next, to impart solemnity and honor to the office.

All of these societies, national and international, devote themselves and their academic endeavors to the research, diagnosis, and care of surgical lesions residing within the child’s nervous system. Specialty-specific journals and multiply authored textbooks dedicated to pediatric neurosurgery have become academic byproducts of these professional bodies.

These organizations have also acknowledged their responsibility for the continuation of specialty education, principles summarized by Concezio Di Rocco in his exhaustive analysis of international education applicable to the specialty.²³ Continuing medical education programs that focus on pediatric neurosurgery have sprung up around the world. Some are topic or technology based, whereas others cover a broad range of issues across the field of endeavor. For example, the education committee of the ISPN organizes academic courses that are held in Third World nations. Meanwhile, in North America, rigorous education and practice standards have been set up for fellowship programs. For several years, the ESPN has conducted triphasic pediatric neurosurgery teaching courses for trainees in Europe.

By the end of the 20th century, pediatric neurosurgery had become an established and recognized subspecialty.

1.3.1 The Establishment of the American Board of Pediatric Neurosurgery and the Formalization of Postgraduate Pediatric Neurosurgical Training in the United States and Canada

As noted previously, the practitioners of pediatric neurosurgery had always demonstrated an unwavering commitment to the

care of pediatric patients and the adequate training of neurosurgeons specializing in the care of children and infants. In the 1980s and early 1990s, it became apparent to many of the leaders in the subspecialty in the United States and Canada that in many North American programs, residents were inadequately trained in pediatric neurosurgery because of limited patient volume and faculty expertise. The majority of established academic and private practice pediatric neurosurgeons agreed that to protect pediatric patients with neurosurgical disorders, standards for the education of pediatric neurosurgeons needed to be established and rigorously supervised. The longstanding question of how one identifies a pediatric neurosurgeon was to be answered by the establishment of an independent board to certify pediatric neurosurgeons based on agreed-upon standards, and to provide a certificate to those individuals who fulfilled the requirements. The goal was nearly accomplished through the standard regulatory channels for the establishment of such credentialing in the United States—namely, a subspecialty certification from the American Council of Graduate Medical Education (ACGME), with the approval of the parent American Board of Neurological Surgery (ABNS). There was great concern among organized neurosurgery, however, that the granting of such a subspecialty certificate would interfere with the clinical practice of neurosurgeons previously certified by the ABNS. Despite the fact that the certification was approved, the mandated requirement of a 2-year period of postgraduate training meant that there were no applications for such certification, and the ACGME and ABNS approval lapsed. Spurred by the knowledge that after many failed attempts to obtain such specialty certification through the usual channels it would never be approved by the current political bodies, a group of prominent American pediatric neurosurgeons, led by David McLone of Chicago, Donald Reigel of Pittsburgh, William Cheek of Houston, and Robert McLaurin of Cincinnati, among others, convened a pivotal meeting at the Chicago O'Hare International Airport in 1996 to define the missions, goals, and structure of the proposed board. They gained a unanimous agreement from the more than 75 pediatric neurosurgeons present to go forward with the creation of what would become the American Board of Pediatric Neurosurgery (ABPNS). This board became the first neurosurgical board to require recertification, and it enumerated requirements for yearly case load and the appropriate pediatric neurosurgical training of diplomates. Concomitantly, the Accreditation Council for Pediatric Neurosurgical Fellowships (ACPNF) was established to regulate and supervise fellowships that were established in North America to train pediatric neurosurgeons, defining the size and composition of faculty, required case volume, composition and quality of the ancillary services at the affiliated pediatric hospitals, and quality of the affiliated residency training programs. In what has been one of the most remarkable aspects of the formation of this independent board and fellowship accrediting body, both the ABPNS and the ACPNF have been widely accepted as the ultimate arbiters in determining the training and qualifications of pediatric neurosurgeons, with the tacit approval of the ABNS to function in parallel with these bodies; the general ac-

ceptance by pediatric hospitals and by academic and private practice centers of the role of the ABPNS and ACPNF in the identification and training of pediatric neurosurgeons was accomplished within 10 years of the founding of the ABPNS.

1.4 Conclusion

The history of pediatric neurosurgery parallels developments in many spheres of surgical practice in the 20th and 21st centuries. At first, the generalist surgeon performed operations on every part of the body; gradually, specialties emerged, and what we now consider expert management of extremely complicated conditions has been fostered by this development. In the past, much time and effort had to be expended to convince hospitals, our colleagues, and our certifying bodies that children are not simply small adults, and that the clinical problems of children are unique and should be treated in unique facilities with unique ancillary services. The individuals over these two centuries who have developed our pediatric neurosurgery subspecialty have been notable for their humanity as well as their clinical and teaching skills, and the present quality of our training and practice remains very much in their debt. It is incumbent on all of us to remember this rich history of pediatric neurosurgery and to recall it to our trainees.

2 Normal and Abnormal Development of the Nervous System

Timothy M. George and David Cory Adamson

2.1 Introduction

Understanding normal development and the consequences of abnormal early embryogenesis remains vital for the surgeon caring for children with congenital nervous system anomalies. In this chapter, we discuss nervous system defects as they relate to particular embryologic events and the mechanisms causing the malformations. However, a complete description of the development of the human nervous system is a Herculean task beyond the scope of this chapter; therefore, we refer the extensive details of neuroembryology to expert texts^{1,2} and the Web site (http://www.med.unc.edu/embryo_images) for excellent images.

It is always important to bear in mind that the central nervous system (CNS) develops in concert with other organ systems (► Fig. 2.1a). In fact, the development of other organ systems is often instructed by proper CNS development and vice versa. As such, maldevelopment of the CNS is typically coupled to malformations of another organ system (► Fig. 2.1b). From a modern embryologic perspective, the mechanisms causing associated malformations must be studied interdependently. This approach allows an examination of the molecular signaling, tissue interactions, cellular differentiation, and cellular orientation that define organogenesis.

The embryopathy for many defects has not been tested experimentally. We are, therefore, left with many speculative and observational theories to explain the embryogenesis of human malformations. We do not exhaustively review all theories here but give the most recent view on embryopathy based on best experimental data. Only when relevant to the embryology does a broader discussion of multiple theories take place. Secondarily acquired CNS pathology, such as hydrocephalus or syringomyelia, is not discussed.

2.2 Molecular Determinants of Congenital Defects

The evaluation of how molecules effect development and disease can be divided into three categories: genomics, the study of DNA and RNA structure and regulation; proteomics, the study of the control and regulation of protein products within the cell and tissue matrix; and metabolomics, the exploration of pathways metabolites use to govern cellular function. Diseases occur as a disturbance of one or more of these areas. Future diagnostics and treatments will be based on the understanding and manipulation of these molecular substrates.

Congenital defects of the nervous system do not fit into simple genetic syndromes but more often embody complex genetic disorders. For example, many regulatory, structural, and enzymatic genes have been implicated in neural tube defects (NTDs).³ Epidemiologic studies of potential environmental risk factors for NTDs have a relatively long history and have identified several factors (e.g., valproate, maternal diabetes, Agent

Orange) that appear to be related to NTD risk. In contrast, the study of genetic risk factors for NTD has a relative short history. Although traditional approaches to genetic linkage (e.g., LOD [logarithm of the odds] score and affected relative pair analyses) have been applied to the study of other conditions since the 1980s, the data required by such approaches (i.e., DNA from multiple affected individuals within families) are largely unavailable for NTDs.

Insights from the human genome project^{4,5} have suggested that the genome represents a complex biochemical machine functioning in three-dimensional space with three distinct and dynamic interacting parts. DNA coding regions, only 2% of the genome, are responsible for blueprinting protein structure, the repository of heritable traits. “RNA only” coding DNA gives rise to *active* RNAs capable of altering the behavior of normal genes. Consequently, studies designed to identify genes that influence the risk for NTDs did not become feasible until the 1990s, when the Human Genome Project began to provide new information regarding the variability within the human genome. Such advances in our understanding of the human genome have provided new opportunities for studying the genetic contribution to conditions like NTDs (e.g., case-control and family-based genetic association studies of non-Mendelian conditions). Another powerful tool in the identification of genes causing NTDs has been candidate gene studies. Although studies of candidate genes in pathways of folate metabolism and non-folate-related candidate genes also have not yielded any genes or genetic variants that are consistently associated with NTD risk, none of the genes that have been evaluated as NTD risk factors has been studied in sufficient detail to warrant its exclusion as a candidate.

Lastly, epigenetic mechanisms may play a role in NTD causation. Epigenetic regulation of gene expression has been suggested to alter the gene function by several mechanisms; these include methylation of DNA at certain C-C dinucleotide repeat segments, with folic acid acting as a chief donor of methyl groups⁸ enzymatic modification of histone function⁹; and activation or suppression of gene function by transposons,¹⁰ also known as “jumping genes.” Since NTDs have been associated with complex patterns of inheritance and are influenced by environmental agents, it is logical to assume that epigenetic effects and not necessarily mutated gene sequences may be very important in the development of neural malformations.

In addition to direct gene regulation, protein and amino acid structure and function can be directly altered, leading to malformations. Protein sequence, conformation, kinetics, modifications, and interactions can all be implicated in abnormal development. Profiles of several groups of functionally related proteins, including circulatory, cytoskeletal, and stress proteins and other proteins of unknown function, have been demonstrated to be important in the developmental regulation of neural tubes of mice and presumably NTDs.¹¹

In the study of metabolic pathways, metabolomics, folic acid pathways have been implicated to influence the risk for NTDs.¹²

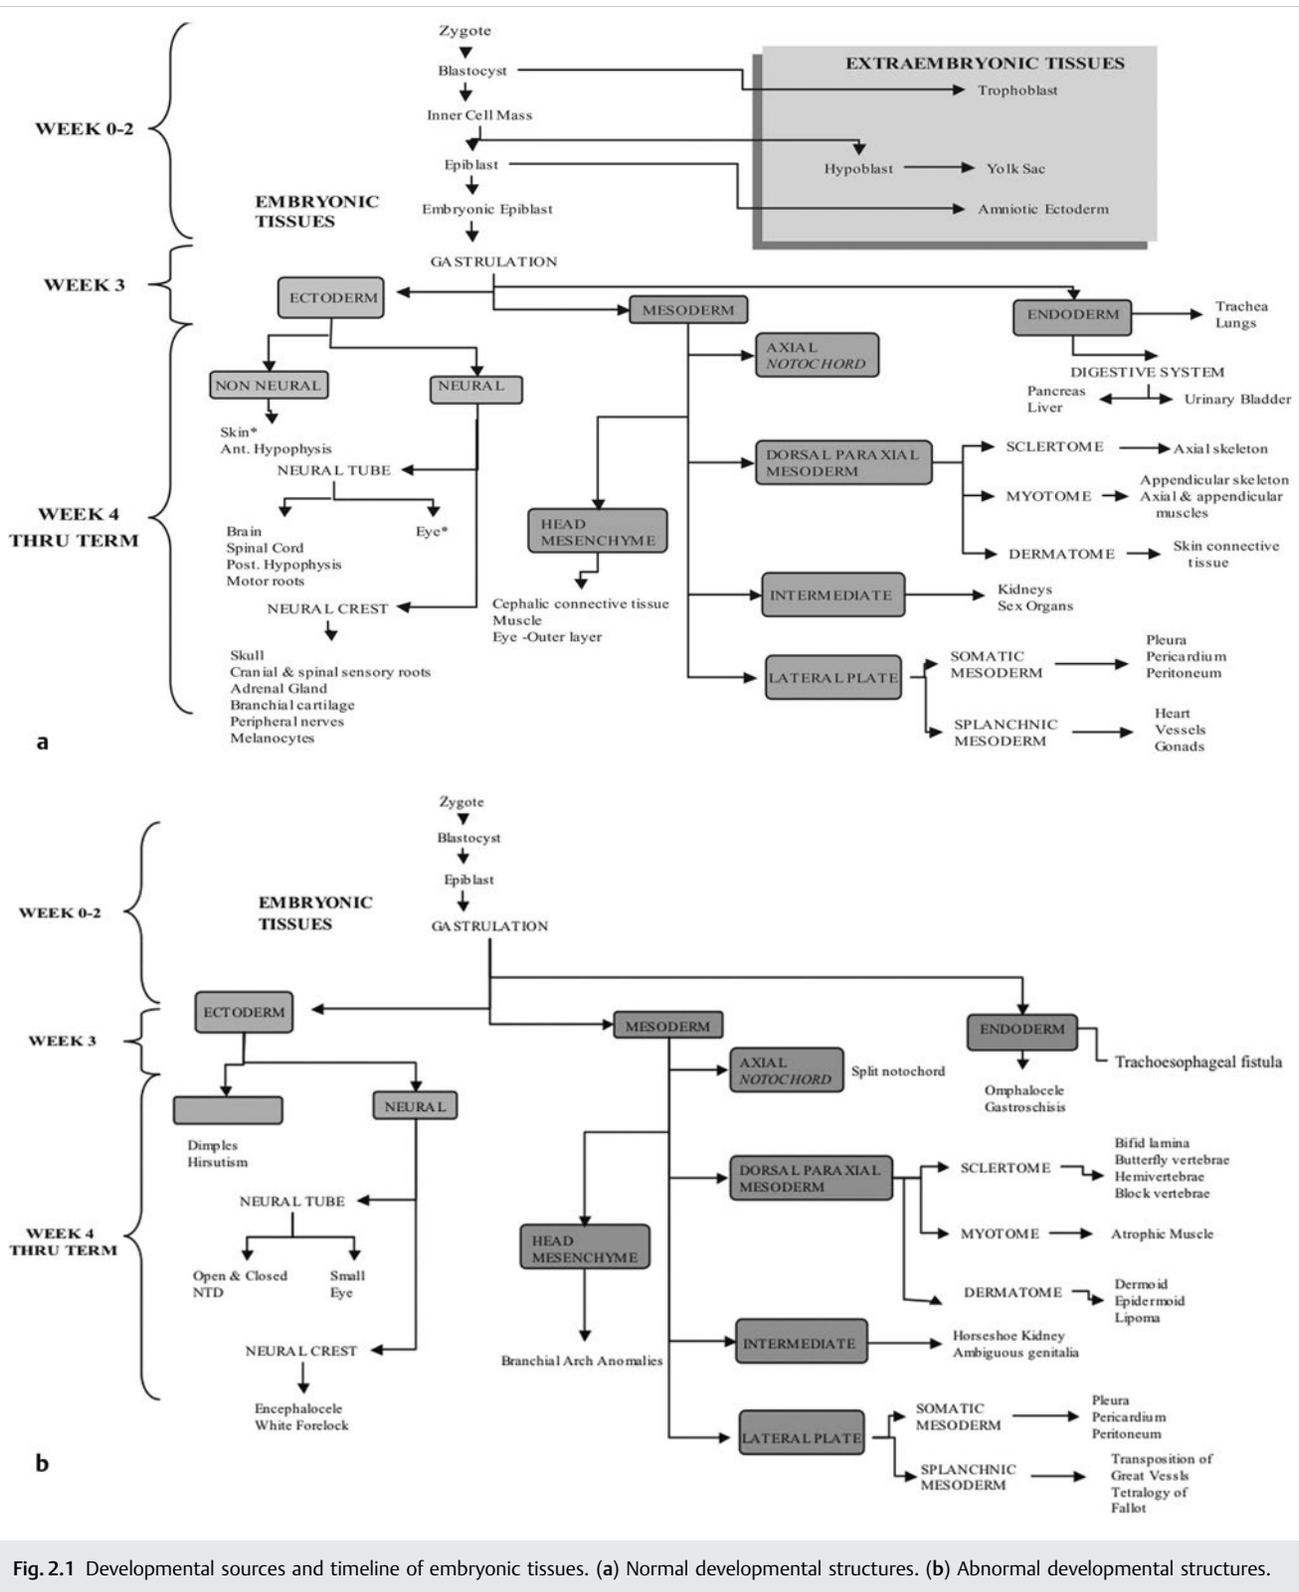

Fig. 2.1 Developmental sources and timeline of embryonic tissues. (a) Normal developmental structures. (b) Abnormal developmental structures.

Studies of mutant enzymes in the folate metabolic pathway, particularly methylenetetrahydrofolate reductase (MTHFR), have suggested a possible association with NTDs.⁷⁻¹¹ The likely role folate plays in the reduction of NTDs resides within the

methylation cycle of homocysteine (► Fig. 2.2). Conversion of homocysteine to methionine occurs when donated methyl groups from folate utilize MTHFR and enzymes that require vitamin B₁₂ as a cofactor. Homocysteine can act as a teratogen

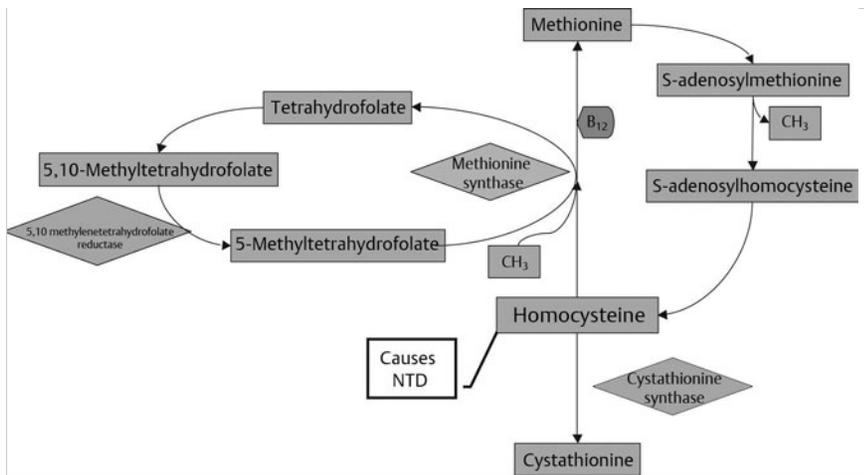

Fig. 2.2 Homocysteine methylation cycle. (Note: Homocysteine perturbs neurulation in experimental animals.) NTD, neural tube defect.

and may be important in human NTDs.^{13–19} The possible association with mutated MTHFR, cystathionine synthase, and altered homocysteine methylation further suggests the importance that folate metabolism may have in human NTDs.²⁰

Currently, whole-genome screening and the bioinformatic processing of genomic data hold the promise of improved molecular analysis of embryologic events. Whole-genome screening has been limited by cost (up to \$10,000 per whole genome), poor understanding of the genome sequence, and the relevance of epigenetic effects. Reduced cost, high-speed genomic sequencing throughput, and better understanding of the genomic and epigenetic impact on disease will change the future of molecular embryology.

2.3 Embryogenesis of the Neuronal System and Malformations

2.3.1 Pregastrulation (Morula and Blastocyst Stages)

During the morula and blastocyst stages, proper cellular orientation or polarity is initially established. By postovulatory day (POD) 5, the embryo has developed from a single fertilized egg, through morulation, and into a 32-cell blastocyst, with an eccentrically placed inner cell mass and a surrounding ring of cells called the trophoblast. The inner cell mass forms the epiblast and the hypoblast, similar to the dorsal (animal) and ventral (vegetal) poles in *Xenopus*.²¹ The epiblast ultimately forms the embryo. These first signs of cell polarity provide the fulcrum for the developing body axis and nervous system induction.

The first obvious feature of rostrocaudal polarity occurs around POD 13, with thickening of the rostral end of the hypoblast into the prechordal plate and the birth of the primitive streak at the opposite end.²¹ The primitive streak elongates cranially in the midline of the embryo and becomes contiguous with the simultaneously developing primitive knot, or Hensen node, at the rostral end. The Hensen node functions as the embryonic “organizer” and is critical to induction of the notochord and neuraxis.

A cascade of factors expressed in a spatially and temporally controlled manner tightly regulates the early steps in the devel-

opment of the body axis. Numerous studies have uncovered several genes implicated in patterning of the primitive body axis; however, the *Wnt1* β -catenin pathway is the most understood.^{22–24} *Wnt1* activates a cascade that increases β -catenin, which directs early expression of target genes, such as *brachyury* and *siamois* (important for proper formation of the primitive streak²⁵), *cripto* (responsible for proper dorsoventral polarity in the epiblast²⁶), and *twin* (required for development of the embryonic organizer²⁷).

In addition, the *Wnt1* β -catenin pathway influences bone morphogenetic proteins (BMPs),^{22–24} which play a significant role throughout neurogenesis but are especially critical during pregastrulation for helping to establish proper rostrocaudal polarity. BMPs subsequently serve as positive inducers of epidermal differentiation during primary neurulation.

Other nonmolecular mechanisms also help to instruct proper axis determination. Proper perpendicular alignment of the embryo with the longitudinal axis of the uterine wall,²⁸ pH and ionic gradients, cell orientation in response to the site of sperm entry into the egg, and/or gravitational forces²² may all affect future embryonic polarity. Clearly, mechanisms governing polarity during pregastrulation are not completely understood; several different processes are most likely involved.

Defects of Pregastrulation

No known malformations occur during the pregastrulation period. Perturbations during these stages would affect the polarity and differentiation of early primordial stem cells, the ability of the embryo to implant properly, and the development of the placenta and critical extraembryonic membranes—all of which would be lethal to the early embryo.

2.3.2 Gastrulation

Establishment of the organizer, primitive streak, and proper embryonic axis marks the beginning of gastrulation, or formation of the three embryonic germ layers (► Fig. 2.3). During gastrulation, a dramatic reorganization of the embryonic cells occurs along the rostrocaudal, dorsoventral, and left–right axes. The initial relationship and orientation of cells established in the blastula are rearranged through coordinated cell move-

ments. Around POD 16, successive waves of epiblast cells caudal to the Hensen node migrate into the primitive streak and form the prospective endoderm and mesoderm. Epiblast cells immediately around the Hensen node migrate into the node in the midline and then rostrally to form the notochord.

The notochord, located between the ectoderm and endoderm, is vital for determining the rostrocaudal axis of the embryo beginning at the anteroposterior (AP) borderline, thought to occur in the region of the hindbrain–midbrain junction (see ► Fig. 2.3). The notochord also intercalates with the endoderm and contributes to the ventral floor plate region of the future neural tube. Another connection, previously known as the neuenteric canal, occurs in the pit of the Hensen node and connects the ectoderm to the endoderm.²⁹

Several genes have been implicated in these early steps of gastrulation³⁰; however, *brachyury* is clearly required for normal gastrulation movements and development of the three germ layers in embryos.³¹ As cells move away from the streak, *brachyury* expression is downregulated, except in the head

region and notochord. Mice that are homozygously deficient in this gene do not form a primitive streak, have an absent or abnormal notochord, and lack caudal mesodermal structures.³¹ Downstream target genes of *brachyury* must include notochord-forming factors, cell adhesion molecules involved in gastrulation movements, and factors needed to continue expression of *brachyury*.

Dorsoventral patterning is an important event during gastrulation and depends on the proper expression of *brachyury* as well as competitive interactions between ventral signals, such as sonic hedgehog (shh) and HNF- β ,³² and dorsalizing factors from the ectoderm, such as BMP-4, Msx-1, and dorsalin-1.^{33–36} As discussed earlier, the formation of dorsal structures also requires the expression of *Wnt*/ β -catenin factors.³⁷

Establishment of left–right polarity is also thought to occur during gastrulation, with formation of the notochord; however, there is no anatomic correlate. Left–right asymmetry may be related to the asymmetric expression of growth and transcription factors during gastrulation. In avian embryos, activin-bB and its

receptor are found only on the right side of the Hensen node, whereas *shh* is expressed only on the left. Similarly, in the mouse, *nodal*, a transforming growth factor- β (TGF- β) protein, and *lefty* are found only in the left-lateral mesodermal plate.^{30,38}

Defects of Gastrulation

Defects during gastrulation are thought to affect all three primary cell layers along all embryonic axes. Malformations include split-cord malformations (SCMs); neurenteric, dermoid, and epidermoid cysts; anterior and posterior spina bifida; intestinal malrotations, duplications, and fistulas; anterior meningoceles; and other complex dysraphic malformations. Additionally, congenital tumors, such as teratomas, may have their origin during gastrulation.

Common to this class of defects is the presence of an SCM (► Fig. 2.4). SCM type I, formerly called diastematomyelia, comprises two dystrophic spinal cords separated by a vertical bony bar with two dural tubes. SCM type II, formerly called diplomyelia, comprises two dystrophic cords separated by a fibrous band contained in a single dural tube. Complex SCM, or type III, occurs when one of the dystrophic hemicords forms an open NTD, also called a hemimyelomeningocele. True dimelia, or complete duplication of a normal spinal cord, has not been described.³⁹ These malformations represent a spectrum of defects of a common embryopathic mechanism. The open NTD associated with an SCM further underscores the likelihood that the SCM developed before the NTD.

Many theories exist to explain the embryopathy of SCMs and more complex defects.^{40,41} The common theme is an underlying embryologic defect involving the formation of two notochordal structures. The notochord is split by a retained or accessory neurenteric tract, or it is split by the persistent separation of primitive paired notochordal anlagen. The separation of the notochord induces the formation of two separate neural plates, and retained tissue between the plates forms a tract or rest of pluripotential cells. Laterally displaced somites lead to vertebral anomalies such as butterfly vertebrae. The intervening tissue

contains pluripotential cells capable of developing all three germ layers, including ectodermal malformations (tufts of hair, dermoid and epidermoid cysts); mesodermal malformations (bony, cartilaginous, or fibrous bands; muscle; adipose tissue; vessels); endodermal malformations (intestinal malrotations, neurenteric cysts); and lesions with all three germ layers, such as teratomas.⁴²

The underlying defect remains unknown, but two basic mechanisms are likely: aberrant axial mesodermal cell movements and duplication of normal axial structures secondary to inappropriate instructive signaling. Aberrant cell movements have been described when the Hensen node is surgically split during late gastrulation in chick embryos.⁴³ Inappropriate migration of the notochord has been reported in *brachyury* mutant embryos.³¹ Duplication of the caudal neural tube and notochord is caused by teratogenic levels of exogenous retinoic acid, antisense oligonucleotide inhibition of *engrailed* genes,⁴⁴ or fibroblast growth factor receptor-1 (FGFR-1) manipulation.⁴⁵

2.3.3 Primary Neurulation

Neural Plate Induction, Lengthening, Folding, and Fusion

Primary neurulation is a complex morphogenetic process comprising several independent events that overlap temporally and spatially. The result is the development of the brain and spinal cord down to the S2 level. It can be divided into four major events: neural plate formation, neural plate midline bending, neural plate lateral wall bending, and neural fold fusion (► Fig. 2.5).

The primordial neural plate is first induced around POD 16 as a pseudostratified columnar epithelium.⁴⁶ The process of *induction* occurs when a group of cells establishes, changes, or directs the development of an adjacent group of cells via direct contact or by the secretion of diffusible molecules.⁴⁷ Neural induction is the default of ectoderm differentiation.³⁶ Neuronal differentiation is actively inhibited in the ectoderm by ventral embryonic cells and early ectoderm.³⁶ It appears that BMP-4 is responsible

for neural inhibition and is blocked in the prospective neural ectoderm by antagonizing molecules, such as chordin, noggin, follistatin, and others.^{24,48-53}

The newly induced neural plate is transformed from a flat, oval structure into a narrow, elongated one. Net cell movement is lateral to medial, along with intercalation in the midline to help lengthen the neural plate in the process known as conver-

gent extension⁵⁴ (► Fig. 2.6). Blocking the gene *dishevelled* can disrupt convergent extension.⁵⁵ *T-box* genes similar to *brachyury* as well as *Wnt* pathway factors also appear important for proper convergent extension to occur.^{56,57} Cellular features accounting for transformation of the neural plate are increases in cell elongation and height, cell division, and cell rearrangement or intercalation.

Around POD 17, a shallow midline neural groove in the neural plate forms directly above the notochord, initiating bending of the plate. Induced cells located in the midline of the neural plate change from a spindle shape to a wedge shape, forming a median hinge point (MHP).⁵⁸ Cell wedging during neural plate bending is brought about by the contraction of circumferentially oriented apical microfilaments via a sliding mechanism utilizing actin and myosin,⁵⁹ along with prolongation of the cell cycle.⁶⁰ The notochord-secreted morphogen *shh* is the primary molecular substrate for this phenomenon.⁶¹ Mouse embryos exposed to cholesterol synthesis inhibitors are thought to produce holoprosencephaly and NTDs through an *shh*-mediated mechanism. Additional bending points, dorsolateral hinge points (DLHPs), occur in the cranial and low primitive spinal cord regions of the developing neural tube. The molecular determinants of DLHPs are largely unknown. DLHPs allow the tips of the neural folds to bend inward toward each other and converge.⁵⁸

Neural fold fusion is poorly understood. Cellular mechanisms include interactions of cell surface glycoproteins, interdigitation of cell surface cilia, and formation of intercellular junctions. A surface coat of glycosaminoglycans (GAGs) becomes more concentrated at the fold tips immediately before fusion.⁶² The composition of GAGs changes during neurulation, with hyaluronic acid predominating before fusion and chondroitin sulfate predominating after fusion.⁶² Cell adhesion molecules (CAMs) and cadherin play a role in the separation of the neuroectoderm from the surface ectoderm. As neurulation proceeds, the neural plate stops expressing E-CAM and begins expressing N-CAM and cadherin.

Cilia have become recognized as important in neural tube closure, likely as mediators of neural tube formation and neural fold fusion. It appears that cilia help mediate hedgehog signal transduction pathways.⁶³ *Gli*-type transcription factor activity downstream is controlled by hedgehog and is important for the patterning of cell fate during embryogenesis.⁶⁴ Animal models with mutant cilia developmental genes have disturbed neural

tube closure.^{65,66} Recently, the *MKS1* and *MKS3* genes have been cloned in the Meckel-Gruber syndrome, which is known to have neural tube defects along with renal and limb abnormalities. The *MKS1* and *MKS3* genes are important in ciliogenesis, implying that cilia are important in neural development.⁶⁷

Toward the completion of fusion, dorsal neural tube cells extend cellular protrusions medially and laterally, bringing about the radial intercalation of deep and superficial cells to form a single cell-layered, pseudostratified neural tube.⁶⁸ Intercellular gaps or tight junction connections are established between cells on apposing neural folds, completing the fusion process.¹ Human neural tube closure occurs between PODs 21 and 28, proceeding from three initiation sites along the neuraxis.⁶⁹ Therefore, the fusion process occurs in multiple discontinuous waves until closure is complete.

Genes such as *PAX3* may be important in neural fold fusion. A paired-type homeobox gene, *PAX3* is expressed in the lateral and posterior neural plate, and expression increases in the dorsal neural tube precisely at the time of neural fold fusion.⁷⁰ Altered *PAX3* function results in NTDs, as seen in the splotch mouse mutant.⁷¹

Extrinsic factors may also contribute to neural tube formation.⁷² These factors include compression of the neural folds by the medial convergence of the surface ectoderm, elevation of the neural folds by the accumulation of underlying mesodermal cells, expansion of the underlying extracellular matrix, and passive buckling of the neural tube by elongation of the notochord and floor plate of the neural tube.⁷³ In addition, newly formed neural crest cells may contribute as they migrate toward the dorsal midline, with two lateral cell groups combining into a single medial population at the roof of the neural tube.⁶⁸

Neural crest cell emigration itself may be a significant determinant of neural tube closure and subsequent dysjunction at the neurocutaneous interface. Neural crest cells are formed from a nidus of cells at the junction of the neural tube and surface ectoderm and migrate laterally after neural tube closure. The *PAX3* and *slug* genes appear to be important in neural crest determination and migration. Human (Waardenburg syndrome)⁷⁴ and mouse (splotch)⁷⁵ mutants of *PAX3* have defects in the migration of neural crest cells. When *slug* is inhibited in chick⁷⁶ or frog,⁷⁷ proper neural crest migration is blocked, and the neural tube fails to close.

Variations in Neurulation along the Rostrocaudal Axis

Neural tube formation is clearly more dynamic and complicated than initially proposed (see ► Fig. 2.5).⁷⁸ At least three different modes of neural tube formation exist throughout the rostrocaudal axis, reflecting different mechanisms. Mode 1 occurs in the cervicothoracic region, where a distinct MHP forms without any evidence of DLHPs. The neural folds remain straight, resulting in an ovoid tube and slit-shaped canal. In the midbrain-hindbrain region, mode 2 occurs, with the appearance of a MHP and DLHPs. After fusion, the tube takes on a diamond-shape configuration, foreshadowing the shape of the fourth ventricle. Neural tube formation in the lumbosacral region, mode 3, involves only a suggestion of DLHP formation in addition to the well-developed MHP, forming a more circularly shaped tube

with a large, patent canal. These neural tube differences may account for some regionally specific abnormalities.

Before the neural tube completely closes, the cranial portion begins to undergo rapid expansion due to increased growth of the tube and enlargement of the ventricular system.⁵² Closure of the cranial neuropore with spinal canal occlusion isolates the ventricular system and increases the intraventricular pressure, which may drive brain enlargement.⁴⁹

The anterior neuropore closes at about POD 24 as a thickening in the dorsal portion of the embryonic lamina terminalis, the future site of the anterior commissure.⁷¹ The caudal neuropore closes at about POD 26,⁴⁹ corresponding to vertebral level S2. It appears that in humans, most of the spinal cord, as far as the S2 level, forms by primary neurulation; the filum terminale and lower sacral levels form by secondary neurulation.

After neurulation is completed, the neural tube is clearly segmented along the AP axis into the various components of the future CNS. An important landmark in nervous system segmentation is the AP borderline that resides in the midbrain-hindbrain junction.⁷⁹ Segmentation is not a function of neurulation but is determined earlier in development by the rostrocaudal gradients of homeotic gene expression. These gradients set in motion the sequential expression of sets of embryonic gap genes, pair rule genes, and segment polarity genes, each set resulting in progressively greater segmentation.⁸⁰

Defects of the Primary Neural Tube (Anencephaly, Cranioraschisis, Myelomeningocele, Myeloschisis)

Open human NTDs (► Fig. 2.7) include the common nonsyndromic anencephaly, cranioraschisis, myelomeningocele, and myeloschisis and reflect a spectrum of defects that occur during primary neurulation. Infants with anencephaly or cranioraschisis do not survive; therefore, these conditions are clinically irrelevant. However, it is imperative that these lesions be understood to discern how the clinically important myelomeningocele and myeloschisis develop. Four developmental mechanisms for open NTDs have been proposed based on data from humans and laboratory animal models: (1) factors important to intrinsic patterning to the neural plate, (2) factors extrinsic to the neural plate, (3) factors important along the rostrocaudal embryonic axis, and (4) reopening of a closed neural tube.

The first concept proposes that open NTDs are the result of an abnormality directly within the neuroepithelium. Studies of patterning and induction of the neural plate have revealed that ventral and dorsal neural plate structures are developed by specific but independent signaling cascades,^{81,82} and they are considered separately in the following paragraphs.

The essential ventral cellular element for neural tube closure is the MHP. Ventral signaling molecules, such as *shh*⁸³ and *HNF-β*,⁸⁴ specify the formation of wedge-shaped cells required for neural plate folding. The phenotype of cranioraschisis in mutant animals, in which the neural tube is open from the level of the midbrain to the lower spinal levels, is thought to be the result of abnormal MHP determination. The telencephalon and midbrain close normally, indicating that the dorsal elements that lead to fusion are normal. In the four mouse mutants with cranioraschisis, *dishevelled*,⁸⁵ *loop-tail*,⁸⁶ *circletail*,⁸⁷ and *crash*,⁸⁸ the neural folds elevate normally but are widely spaced at the

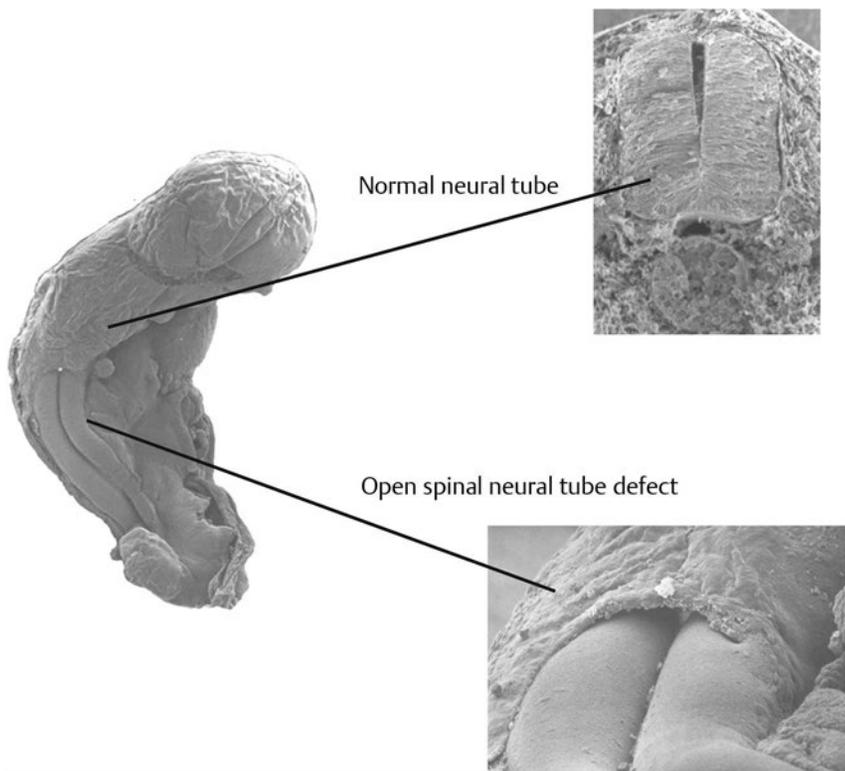

Fig. 2.7 Open spinal neural tube defect. Note how the medial hinge region is normal and cutaneous ectoderm remains attached at the lateral borders of the neural plate.

initial closure site. At the cellular level, abnormal neural plate development in cranioraschisis resulted from disturbed convergent extension, a consequence of disturbed *Wnt* signaling pathways.⁵⁵ Disturbed convergent extension yields a shortened and broad neural plate, and thus a widened and misshapen MHP. The relevance of this model is that neurulation in the hindbrain and upper spinal cord depends on proper MHP development, and any abnormality affecting MHP development is likely to be lethal in humans.

Critical dorsal neural plate determinates for neural tube closure are the proper formation of the DLHPs and the fate of roof plate precursors. Animal models with dorsal neural plate abnormalities have cranial defects, lower spinal defects, or a combination. The key mouse mutant for this model is the *splotch-PAX3* mutant.⁷⁵ In humans, *PAX3* is defective in patients with Waardenburg syndrome, with a subset having spinal NTDs.⁷⁴ The *PAX3* gene is expressed in the presumptive dorsal neural plate, neural crest, and paraxial mesoderm that gives rise to skeletal muscles.⁸⁹ In the *splotch* mouse, the MHP is normal, but the DLHP region is not. This has been confirmed in chick embryos treated with antisense oligonucleotides to *PAX3*.⁷¹ It is not known how mutant *PAX3* causes NTDs; increased apoptosis,⁹⁰ faulty pyrimidine synthesis, or alterations in cell migration^{91,92} have been proposed.

In addition, altered function in neural crest precursors of the presumptive roof plate may alter neural tube closure. *Splotch* demonstrates repressed neural crest migration activity. Chick embryos treated with antisense oligonucleotides to *PAX3*⁷¹ or *slug*,^{76,93} important in neural crest precursor migration, demonstrate open spinal NTDs.

The second concept proposes that properties extrinsic to the neural tube are responsible for open NTDs. The best model is the

curly tail mouse, which develops a lumbosacral myelomeningocele and is a phenocopy of nonsyndromic NTDs in humans.⁹⁴ The inheritance, genetics, and response to periconceptual vitamins make this an attractive model for human caudal NTDs. At the tissue level, mutant curly tail embryos exhibit a cell type-specific abnormality of cell proliferation that affects the gut endoderm and notochord, and not the neuroepithelium.⁹⁵ The reduced rate of ventral embryonic cell proliferation results in a growth imbalance between ventral gut primordia and dorsal neural elements. The result is a delay in posterior neuropore closure because of abnormal caudal flexion, resulting in spinal NTDs.⁹⁶

The third concept is based on the location of the NTD as determined by rostrocaudal patterning. One common theme when the location of the defects appears to respect the restricted gene expression along AP axis domains established during gastrulation. The establishment of an AP borderline determines mesodermal and ectodermal tissue specification and gene expression. This transition zone exists between the midbrain–hindbrain boundary and is defined by rostral expression of *otx* genes and caudal expression by *engrailed* and *hox* genes.⁷⁹ At the tissue level, the variation of gene expression along the rostrocaudal axis mirrors the variation in mechanisms of neural fold elevation, folding, and fusion (see ► Fig. 2.5). According to the model proposed by Shum and Copp,⁷⁸ regional rostrocaudal differences in modes of neural tube closure will cause different types of open defects. Defective mode 1 causes cranioraschisis by interfering with MHP formation. Defects of mode 2 cause exencephaly due to defective DLHP function. Mode 3 defects cause open spinal NTDs.

Additionally, many mutant mouse models have demonstrated that the number and location of the NTDs can vary along the neuraxis. For example, *patch*, *PAX3*, and *short-tail*

mutants have defects localized caudal to the AP borderline, whereas *apoB*, *hox-a1*, and extra-toes mutants have defects rostral to the AP borderline. Several mutants with craniorachisis have defects spanning the entire neuraxis.

The last mechanism proposes that a properly neurulated neural tube can be reopened. The only spontaneous mutant in which this mechanism occurs is the curtailed mouse, in which increased cerebrospinal fluid pressure is thought to rupture a thinned roof plate and dermis in the absence of competent dorsal bony vertebrae.⁹⁷ Although the curtailed mutant may indeed have a reopening of a previously closed neural tube, this mechanism seems unlikely in human NTDs.

However, the reopening model is relevant for the neurosurgeon because the animal experiments that formed the basis for fetal repair of the myelomeningocele were predicated on a surgically generated “reopening” model.⁹⁸ In the animal models tested, repair prevented intrauterine injury from either the toxic effects of amniotic fluid or direct intrauterine trauma.⁹⁹ Regardless, no clear correlation can be made between the structural defect in these animal models and what occurs naturally in human myelomeningocele.

The Myelomeningocele Placode

Understanding the embryology of the myelomeningocele placode is of vital importance when novel repair strategies like intrauterine closure and spinal cord regeneration are considered. The placode has been described as a partially functional or nonfunctional remnant of the unneurulated spinal cord, and little is known about the cellular patterning or connectivity within the placode. The placode has preserved dorsal and ventral cord elements—for example, nerve roots and ganglia—but the exposed neural tissue demonstrates hemorrhages and abrasions indicative of injury.¹⁰⁰ The placode exhibits abnormal cellular patterning along the dorsoventral and rostrocaudal axes, indicative of a change in pattern determination with a paucity of maturing neurons.¹⁰¹ Surgical repair will be predicated upon uncovering the true nature of the structure and function of the neural placode.

Other Defects of the Primary Neural Tube (Meningoceles)

Malformations like meningoceles, cervicothoracic meningoceles and myelomeningoceles, and meningocele manqué are completely or partially skin-covered and are not generally grouped with open defects.¹⁰² However, these lesions should be considered defects of primary neurulation. There is often evidence of limited dorsal myeloschisis in which the dorsal neural tube fails to fuse but neurocutaneous dysjunction occurs normally. Patients usually have normal neurologic function; therefore, it has been presumed that the patterning of the spinal cord is also normal. The molecular, cellular, and tissue-specific mechanisms for the development of these malformations are not known.

Defects Involving the Dorsal Ectoderm (Dermal Sinuses, Dermoid Cysts, Epidermoid Cysts)

Dermal sinuses and dermoid and epidermoid cysts can involve any level of the neuraxis, from the most rostral cranium to the

caudal sacrum. Dermoid cysts include elements of mesoderm and ectoderm (skin, hair, sweat glands, and sebaceous glands), whereas epidermoid cysts are composed only of ectodermal elements (squamous epithelium). Dermal sinuses can be associated with tufts of hair. Whether or not to include coccygeal dimples in the spectrum of dermal sinuses is unclear. It is not clear if these are the remnant of the regressed primitive pit or a forme fruste of a dermal sinus overlying the caudal part of the spine. Since dermal sinuses can be associated with SCMs and completely neurulated CNS structures, it remains unclear if these are disorders of gastrulation or late primary neurulation.

The most discussed mechanism involves incomplete dysjunction of the neurepithelium from the cutaneous dorsal ectoderm (► Fig. 2.8). It is thought that incomplete dysjunction occurs at one of the closure sites of the neural tube. There remains a persistent attachment between the neurepithelium and surface ectoderm. What governs dysjunction of the surface ectoderm from the neuroectoderm after neural tube closure is not completely known, but several possibilities exist, as previously discussed.

2.3.4 Secondary Neurulation

Secondary neurulation is less understood than primary neurulation and begins at POD 25 to 27. The secondary neural tube continues as an extension of the primary neural tube as it grows caudally from the region of the posterior neuropore. It is important to view secondary neurulation as part of the sequence of events in the development of the embryonic tail. Therefore, mechanisms that determine mesodermal and neural elements are intimately linked together.

In mammals and birds, the secondary neural tube arises from cavitation, not from folding of the neural plate as at more rostral levels. Descriptively, the process of cavitation involves the development of a central core of cells called the medullary cord. The outer cells of the medullary cord elongate and become radially arranged columnar cells, probably as a consequence of microtubule changes. A central core of haphazardly organized cells undergoes apoptosis, accounting for much of the cell loss and lumen formation during secondary neurulation.

Fate mapping studies have suggested that rostrocaudal organization may represent a continuous program between primary and secondary neurulation, and that it functions in concert with caudal regression of the primitive streak and mesodermal precursors (► Fig. 2.9). Instead of the classic description of mesenchymal to epithelial transformation, it appears that secondary neural tube cells migrate in stereotyped predetermined pathways from rostral proneural structures.¹⁰³ Therefore, primary neurulation and secondary neurulation appear to involve similar morphogenetic movements; however, in contrast to what occurs in primary neurulation, extensive bilateral cell mixing is observed on the dorsal side in secondary neurulation.¹⁰⁴ The cell movements of the secondary neural tube resemble the movements of convergent extension and may be regulated by *PAX3–Wnt* interactions.¹⁰⁵

Beginning around POD 43 to 48 and continuing through early postnatal life, the caudal neural tube undergoes morphogenetic changes leading to conus medullaris ascension.² This occurs by retrogressive differentiation, in which the caudal neural tube loses much of its diameter and fails to develop a distinct mantle

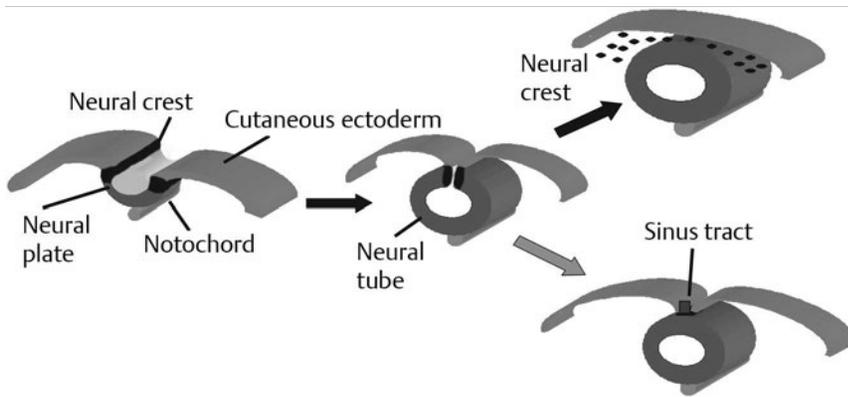

Fig. 2.8 Sinus tract formation; schematic of incomplete dysjunction of ectoderm after neural tube closure.

zone, as well as differential growth of the spinal cord and adjacent vertebral column.² The final position of the conus medullaris is between vertebral levels T12 and L1–L2.¹⁰⁶

Genetic mechanisms for secondary neurulation are still largely unknown. Mutant mice have shown that *brachyury* and components of the *Wnt* signaling pathway control cellular migration and the promotion of mesoderm formation in the caudal embryo. Midkine, a growth factor with neurotropic activity, is one of the few proteins implicated in secondary neurulation.¹⁰⁷ *Brachyury*, *Wnt*, and midkine are thought to regulate secondary neural tube formation by affecting caudal inducing signals. Altered *PAX3* expression may play a role in secondary neural tube by affecting neural crest migration or by maintaining inductive-signaling competence in the neural plate.¹⁰⁸ In addition to the above factors, retinoids have been demonstrated to influence caudal cell movements.^{79,105} In humans, mutation in the *HLXB9* transcription factor causes an autosomal-dominant form of sacral agenesis and may be important in the caudal migratory process of mesodermal precursors. Instructive caudal signals and responsive caudal neural plate elements are needed for proper secondary neural tube formation.

Defects of the Secondary Neural Tube (Abnormal Filum Terminale, Terminal Lipoma, Myelocystocele)

Secondary neural tube anomalies can occur independently or be associated with malformations of primary neurulation, gastrulation, or the caudal cell mass or with mesodermal malformations. Impairment in proper stereotyped morphogenic movements of the caudal neural plate and regressing primitive streak likely accounts for anomalies of the filum terminale and conus medullaris (see ► Fig. 2.9). Pathologically, an abnormal filum can be composed of adipose, fibrous, nervous, or muscle tissues that are derived from secondary neural tube and primitive streak mesodermal precursors.^{109,110} The abnormal tissue is located closer to the conus medullaris because it fails to migrate away to its proper position.¹¹¹

Whereas abnormalities of the filum appear to result from impaired migration, it is likely that the myelocystocele results from improper differentiation and cell fate determination of axial caudal structures. The myelocystocele consists of a dilatation of the caudal central canal of the spinal cord into a glia- and

ependyma-lined cyst surrounded by an expanded terminal spinal cord with an associated lipoma. The terminal dural sleeve is also dilated, producing a double saccular structure. The frequent association of the myelocystocele with other caudal malformations—for example, as part of the VATER (vertebral anomalies, imperforate anus, tracheoesophageal fistula, renal anomalies) or OEIS (omphalocele, cloacal exstrophy, imperforate anus, spinal anomaly) complex—further suggests that this malformation is induced at a time when the fate of the caudal cell mass and terminal spinal cord is being determined.

Defects Involving Dorsal Mesoderm (Spinal Lipomas)

Spinal lipomas include the intraspinal lipoma and lipomyelomeningocele. The intraspinal lipoma lies within the dural sac and typically involves the lumbosacral spinal cord. In the lipomyelomeningocele, the lipoma intercalates into the dorsal spinal cord but additionally extends through a meningeal defect, bifid lamina, and lumbodorsal fascial defect to rest in the subcutaneous tissue. The lipomyelomeningocele is believed to arise during primary neurulation, but the exact timing is not clear. Naidich et al¹¹² proposed the theory of premature dysjunction leading to this defect (► Fig. 2.10). The cutaneous ectoderm prematurely separates from the neuroepithelium, allowing the incarceration of undifferentiated mesenchyme that would normally form meninges or fibroblasts. Key mysteries in these disorders include the source of the adipose cells and how these cells ingress into the developing spinal cord.

One problem with the theory of premature dysjunction is that the surface ectoderm is attached to the dorsal third of the closing neural tube. Once the neural folds come into apposition, the surface ectoderm separates from the neuroepithelium to permit final fusion into the neural tube. This implies that for premature dysjunction to occur, the surface ectoderm has to begin to separate very early in neural fold elevation and folding. Early separation may affect external forces needed for closure of the primary neural tube and result in an unneurulated spinal cord.^{38,61} Dorsal signals from ectoderm important in dorsal neural tube development, such as BMPs, would probably be abnormal if the ectodermal–neuroepithelial interaction was disturbed. Abnormal dorsal signaling would result in more widespread abnormalities in the dorsal neural tube than are seen in typical malformations.

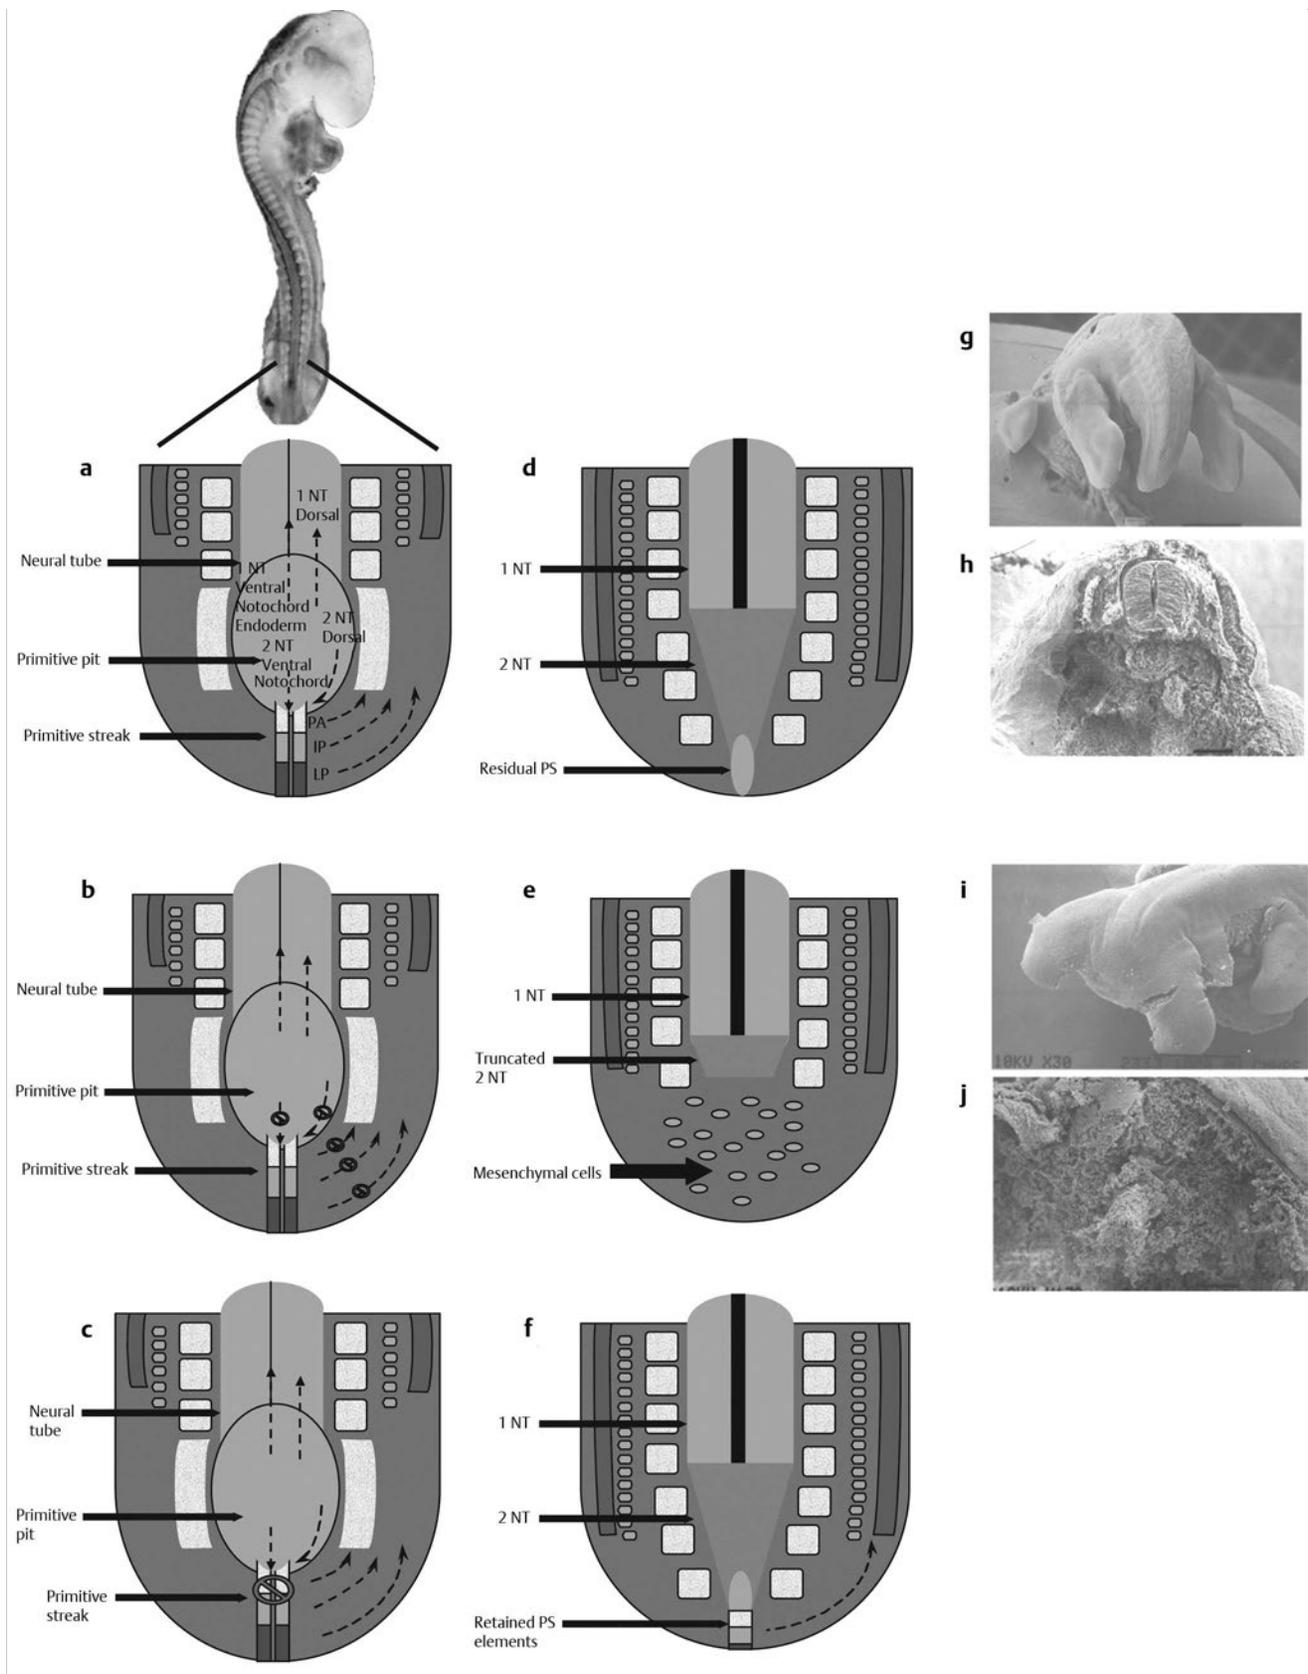

Fig. 2.9 Secondary neurulation, cell movements, secondary neural tube, and tail defects. NT, neural tube; PS, primitive streak.

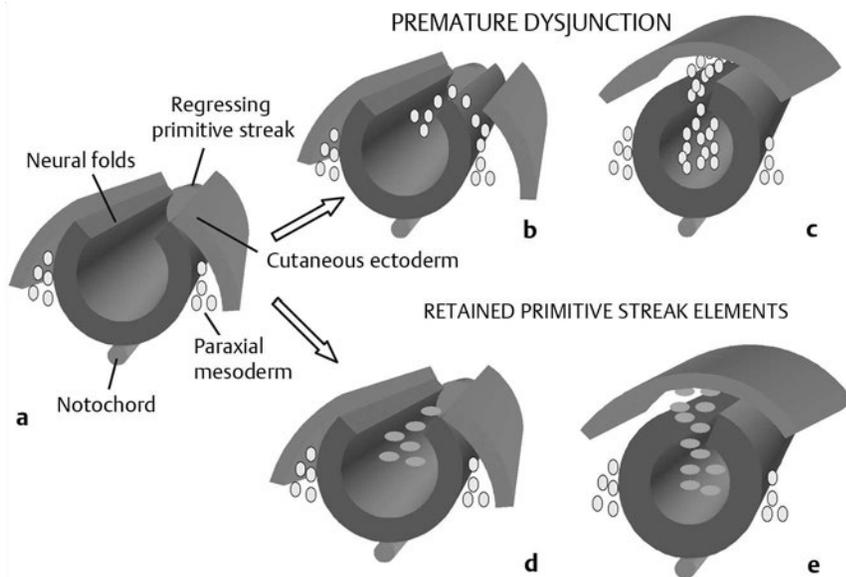

Fig. 2.10 (a–e) Mechanisms of spinal lipoma formation. (b,c) Paraxial mesoderm migrates into the neural tube after the ectoderm separates prematurely. (d,e) Retained caudal primitive streak elements fail to migrate and are retained in the neurulating spinal cord.

Contrary to what was previously thought, adipocytes typically do not arise from meninges, vessels, or glial cells, and spina bifida cannot be explained by the incarceration of mesodermal tissues during primary neurulation or developmental defects at the level of the tail bud.¹¹³ Although adipocytes can be derived from fibroblasts,¹¹⁴ multiple problems exist with this theory based on current data on cell fates. At the stage when the neural tube is closing and premature dysjunction would occur, the fate of the mesenchymal cells comprising the paraxial mesodermal anlage has not yet been determined. This implies that if a lesion did develop, it should be composed of elements derived from this paraxial mesoderm (dermatome, myotome, sclerotome) instead of only adipocytes or fibroblasts.

It has been demonstrated that the dorsal paraxial mesodermal differentiation responds to specific inducers of cell fate (► Fig. 2.11). The dorsal neural tube, ectoderm, and lateral plate mesoderm induce the somite to differentiate into the dermatome and myotome, likely from mesodermal signaling molecules such as *Wnt* and BMPs. The ventromedial region of the somite is induced by ventralizing signals, such as *shh*, from the notochord and ventral neural tube to form sclerotome. Neither *Wnt*¹¹⁵ nor *shh*¹¹⁶ induces adipocytes, but BMP-2 has been shown to induce adipocytes under the proper permissive conditions.¹¹⁷ Therefore, for the dorsal mesodermal anlage to become adipocytes, an inducing signal such as BMP-2, a responsive mesoderm, and/or a factor that prevents normal differentiation would have to be present.

Another mechanism is that mesenchyme from regressing primitive streak becomes retained within the lumen of the folding caudal neural tube by failing to migrate to a specified caudal position (see ► Fig. 2.10). This mechanism does not require abnormal dysjunction. Instead, the retained cells inhibit proper neurulation and meningeal, dorsal vertebral, and paraspinous muscle midline fusion. These cells are destined for a mesoder-

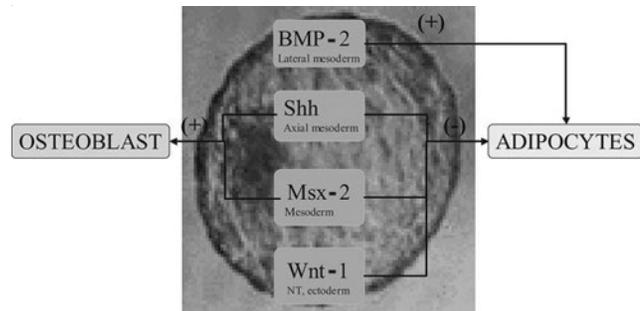

Fig. 2.11 Genes that regulate mesoderm differentiation into adipocytes. NT, neural tube.

mal fate and would then lose caudal repressive *Wnt* signals and respond to lateral mesodermal signals that induce an adipocytic fate. Additionally, retained mesoderm occurs with an improperly migrated primitive streak that leads to the frequently associated abnormalities of the filum.

Defects Involving the Caudal Cell Mass/ Primitive Streak (Caudal Agenesis, Caudal Regression, Sacral Agenesis)

Caudal agenesis, sacral agenesis, and caudal regression syndrome are synonymous terms that describe nonsyndromic malformations ranging from partial to complete absence of the coccyx and sacrum or of the spine up to the lower thoracic vertebrae. Although four patterns of caudal agenesis have been described, two variants of caudal agenesis are most relevant to neurosurgeons: type I, a truncated and high conus medullaris, and type II, a tethered and low conus medullaris that may require a

tethered cord release. All forms of caudal agenesis represent variations of the same mechanism and consist of malformations encompassing all three germ layers (see ► Fig. 2.9). The association of caudal agenesis with the genetic malformation syndromes VATER and OEIS further implicates involvement of all three germ layers. Caudal agenesis is often associated with anomalies of secondary neural tube development, such as lipomas of the filum terminale.¹¹⁸⁻¹²⁰

The caudalmost part of the embryo is still undergoing gastrulation as the primitive streak regresses during tailbud anlage stages of development. The main developmental defect in these malformations is failure or interruption of caudal regression of the primitive streak. Failure of proper migration of cells from the primitive streak produces a shortened embryo and rumplessness in experimental chick embryos.

Disturbance of secondary neurulation, seen as a truncated conus medullaris, is commonly associated with caudal agenesis. It can be presumed that the permissive environment for the continuation of caudal cell movements involved in secondary neurulation is arrested during improper primitive streak regression. Direct evidence for inductive signals for the secondary neural tube has not been described; however, faulty notochord and caudal cell mass development is associated with partial or complete secondary neural tube formation in several mutants. In humans, this phenomenon is seen in sacral agenesis in association with an abnormal T-locus (*brachyury*).¹²¹

Embryology of the Tethered Cord

Tethered spinal cord is a clinical syndrome in which traction on the spinal cord leads to functional deterioration.¹²² Spinal dysraphisms are the source of tethering in this syndrome. Traction leads to stretching of the spinal neurons and microvascular ischemia, resulting in neuronal dysfunction. What makes the spinal cord susceptible to the effects of traction remains poorly understood. In dysraphic defects, it is clear that the spinal cord has significant patterning abnormalities. Developmental data suggest that abnormalities in secondary neurulation result from improper caudal cell migration.¹⁰³ This implies that the distal conus also may be abnormal.¹²³ Examination of the distal spinal cord and tethered filum demonstrates changes suggesting that the distal cord may be abnormal along with the filum.¹¹⁰ Conus and distal spinal cord abnormalities may make these structures susceptible to the forces transmitted by the tethered filum.

2.3.5 Postneurulation Development

Neural Crest

The ectoderm-derived neural crest cells begin to appear around POD 20 in the mesencephalic and rhombencephalic regions and continue to appear along the more caudal neuraxis until POD 32.³² These cells migrate laterally in a dorsal or ventral pathway, and they eventually differentiate into a variety of markedly dissimilar cell types. A cranial neural crest cell population gives rise to the craniofacial mesenchyme (cartilage, bone, cranial

neurons, glia, and connective tissues of the face), thymus, tooth primordium, inner ear cartilage, jaw, primary meninx that forms pia and arachnoid, cranial Schwann cells and melanocytes, cranial nerve ganglia, optic primordium, and optic sheath.^{29,124,125} Truncal and sacral cell populations migrate laterally to form truncal melanocytes, peripheral nerve Schwann cells, primary meninx of the spinal cord, dorsal root and autonomic ganglia, and the adrenal medulla.¹²⁶ Factors involved in the migration and terminal differentiation of these pluripotent cells have been extensively reviewed.¹²⁷

Axial Skeleton

The vertebrae develop from the sclerotome, mesenchymal cell populations derived from ventral somites. The somites themselves are segmentally repeating cell populations of paraxial mesoderm. Somite formation appears to be largely driven by *hox* gene expression, similar to the *hox*-driven segmentation and development of the neural tube. Disruption of the gene pathways necessary for establishing somite divisions results in perturbed somite and vertebral column segmentation; however, the somites that do form will continue to develop into regionally specific sclerotomes and dermamyotomes.¹³²

Sclerotome cells that contribute to the vertebral column migrate to surround the axial midline neural tube, condense, and differentiate into chondrocytes, forming a cartilaginous skeletal framework that is later replaced by bone. The notochord is essential not only for future neuraxial development but also for induction of the sclerotomes and subsequent differentiation of the cartilage forming the vertebral bodies and intervertebral disks. These functions of the notochord appear to be mediated by *shh*.¹³³ Additionally, the products of *pax1* and *MFh1*, expressed in the developing sclerotome, are required for proper vertebral column development. Embryos lacking these gene products lack structures dorsomedial to the vertebral column, develop spina bifida and myelomeningoceles, and have missing vertebral bodies and disks.¹³⁴

The basiocciput develops from mesodermal contributions limited to the occipital and otic regions of somite mesoderm.¹³⁵ Genes, such as *pax1*, have been found to be particularly important at the cervico-occipital transitional zone at the first five somites.¹³⁶⁻¹³⁸ The *pax1* gene is strongly expressed in the region surrounding the notochord and remains until the cartilaginous anlage of the basioccipital bone has developed.¹³⁹ The fusion of the dens axis with the body of the axis also coincides with switching off of the *pax1* gene.¹³⁹ Anomalies of basiocciput segmentation and fusion may account for a small posterior fossa and Chiari malformations.

Postneurulation Defects

Encephaloceles

An encephalocele is a skin-covered herniation of fairly well-organized brain tissue through a defect in the skull. Microcephaly is common, and hydrocephalus can occur but is likely a

consequence of the defect rather than a cause. It is generally believed that the defect occurs during the postneurulation period of rapid brain growth. Therefore, these lesions should not be classified as NTDs. Impairment in chondrocranial growth from an impairment of mesenchyme allows the brain to herniate in animal models.¹⁴⁰ Encephaloceles have been described in the forebrain overgrowth mouse mutant and localized to chromosome 10, but the gene has not been sequenced.¹⁴¹ Multiple teratogens and environmental factors have also been implicated.^{142,143}

Chiari Malformations

Chiari malformations are a group of defects affecting the cerebellum and brainstem. Three primary types have been described, types 1 through 3. Recently, clinicians have defined two more types of Chiari malformation: types 0 and 1.5. In type 0, there is little to no cerebellar herniation but an associated syringomyelia that regresses after posterior fossa decompression.^{144,145} Chiari type 1.5 describes a more severe form of Chiari type 1 in which descent of the medulla below the foramen magnum is seen in addition to a prominent cerebellar tonsillar herniation.¹⁴⁶ The controversial and rare Chiari type 4 (cerebellar hypoplasia) is often excluded but is associated with a small posterior fossa. It is important not to confuse secondary hindbrain herniation (hydrocephalus, tumors, lumbar cerebrospinal fluid diversion) with the primary types.

It remains unclear whether the three types have a common embryopathy. The common theme is an abnormally small posterior fossa. The degree of brainstem or cerebellar hernia may be due to physiologic factors; indeed, two theories have been proposed concerning Chiari type 2 malformations. The hydrocephalus hydrodynamic theory proposes that fetal hydrocephalus leads to an imbalance between supratentorial and infratentorial compartments, causing downward displacement of the hindbrain. The second theory, the traction model, proposes that the spinal cord is tethered, as in myelomeningocele, pulling the hindbrain caudally. Because the hindbrain hernia is reduced after fetal myelomeningocele repair, this theory has credence but does not explain other findings in Chiari malformations. Dysgenesis has been proposed to be the cause of the associated cortical findings in Chiari malformations and focal brainstem dysfunction. Furthermore, segmentation and segment identity genes have been implicated in the development of Chiari malformations because of the commonly associated skull base and upper cervical spine segmentation anomalies.¹⁴⁷

2.4 Editor's Comments

The authors describe our current understanding of the interactions of genes, proteins, and the resultant normal and abnormal neural development. They provide evidence that contradicts the classic teaching that the secondary neural tube develops from the transformation of caudal mesenchymal tissue to neural tissue and that lipomeningocele develops as a result of premature dysjunction. Despite burgeoning genetic knowledge, our understanding of most embryopathies remains “embryonic” but is maturing rapidly.

Pearls

- Maldevelopment of the CNS is typically coupled to malformations of another organ system.
- Induction plays an important role in neurodevelopment and occurs when a group of cells establishes, changes, or directs the development of an adjacent group of cells via direct contact or by secretion of diffusible molecules.
- Defects during gastrulation affect all three germ layers and include split-cord malformations; neurenteric, dermoid, and epidermoid cysts; spina bifida; intestinal malrotations, duplications, and fistulas; anterior meningoceles; other complex dysraphic malformations; and possibly congenital tumors such as teratomas.
- Primary neurulation is a complex process resulting in the development of the brain and spinal cord down to the S2 level, and can be divided into four events: neural plate formation and elongated by the process of convergent extension, neural plate midline bending, neural plate lateral wall bending, and neural fold fusion.
- Closure of the cranial neuropore with spinal canal occlusion isolates the ventricular system and increases the intraventricular pressure, which may drive brain enlargement.
- The closed anterior neuropore becomes the future site of the lamina terminalis.
- Nervous system segmentation in the antero-posterior axis is determined by the rostrocaudal gradients of homeotic genes such as gap genes, pair rule genes, and segment polarity genes.
- Open neural tube defects include anencephaly, craniorachischisis, myelomeningocele, and myeloschisis and reflect a variety of defects along the rostrocaudal axis during primary neurulation.
- Defects involving the dorsal ectoderm (dermal sinuses, dermoid and epidermoid cysts) likely results from incomplete dysjunction.
- Defects of secondary neurulation include abnormal filum terminale, terminal lipoma, and myelocystocele.
- Lipomyelomeningocele is believed to arise during primary neurulation, possibly by the process of premature dysjunction.
- The various types of Chiari malformations are likely embryologically different and require different clinical care.

3 Neurologic Examination of the Newborn, Infant, and Child

Michele Yang and Michael Painter

The ability to perform a thorough neurologic examination and to interpret the findings often obviates the need to perform imaging studies. Our purpose in this chapter is to facilitate understanding of the neurologic examination of children. For purposes of organization, the chapter is organized by age: examination of the newborn (0 to 4 weeks), the infant (1 to 24 months), and the older child (older than 2 years).

3.1 Components of the Neurologic Examination

3.1.1 Screening Methods

Interpretation of the neurologic examination findings depends on a thorough knowledge of normal childhood development. Examination of the term and preterm infant primarily reflects brainstem function and spinal cord reflexes, whereas examination of the older child approximates that of an adult. Maturation of the central nervous system (CNS) proceeds in a rostral to caudal fashion. For instance, head control develops first, with only a slight head lag on pull-to-sit at 4 months of age. The infant is able to sit supported at 6 months and then is able to pull to stand at 9 months. A video review of the neurodevelopmental milestones and the accompanying examination is available online at http://library.med.utah.edu/pedineurologicexam/html/home_exam.html.¹

Screening methods have been developed to assist the clinician in identifying those patients with developmental delays. The clinician has several screening tools at his or her disposal to screen for developmental delay. Each may identify different populations of children with developmental delay because each is characterized by different standardizations, comparison groups used for sensitivity and specificity, and population risk status.² For the purposes of a neurosurgical visit, broad general screening tools that address the main domains of fine and gross motor skills, language, adaptive behavior, and social skills are probably the best to use. There are two types of tools: directly administered scales, such as the Bayley Infant Neurodevelopmental Screen and the Denver-II (Glascoe), and questionnaires given to the family to complete, such as the Ages and Stages Questionnaires.³⁻⁵ The advantages of using these screening tests are that norms are stated explicitly and that normal development within each category is reassuring. However, as they reflect a snapshot in time of a child's development, they may not identify children with mild delays. Parent-based questionnaires may be better screens for mild developmental delay. Several studies have shown that parental reporting of current skills is predictive of developmental delay.⁴⁻⁶ The advantage of screens that rely on parental information is that they do not rely as heavily on the examination of a child who may be sick, afraid, drowsy, or noncompliant at the time of the visit.

In the school-age years, specific underlying abnormalities, such as learning disabilities, may become manifest as school

performance demands cognitive levels not assessed by screening tests. Cognitive development can be assessed, albeit imperfectly, by IQ testing, which can be a predictor of attention, social skills, maturational level, and intelligence. The Wechsler Intelligence Scale of Children-III, which tests verbal, performance, and full IQ, is the most commonly used measure of a child's intelligence. It is used for children ages 6 to 16 years, but some tasks may be difficult for children 6 to 7 years of age. Detailed neuropsychological testing may be necessary to evaluate cognitive function further.

Examiners should be cautioned, however, that a "normal screen" does not preclude subtle developmental abnormalities, as these screens focus narrowly on discrete milestones and do not assess fine detail within those parameters. In addition, a developmental screen assesses the patient's current developmental level and is not a predictor of future achievements or maximal potential. The real value of screening is to follow developmental milestones and to assess if a particular neurologic symptom is static or progressive over time.

3.1.2 History

In a neurologic examination, the examiner begins by taking the patient's history, which includes an outline of the evolution of the illness, its character, and the presence of similar illness in family members. The examiner attempts to establish neurologic disorders as progressive, intermittent, static, or saltatory. Static abnormalities noted in the first few months of life suggest congenital abnormalities or brain injuries sustained during the perinatal period. Progressive disorders suggest degenerative CNS disease, whereas abnormalities that are intermittent and alternate with return to normal neurologic function indicate paroxysmal disorders, primarily seizures. Saltatory disorders, characterized by exacerbation and partial recovery, are seen particularly with demyelinating and vascular diseases and with mitochondrial disorders.

Medical History

The medical history in the evaluation of children begins with the birth history. A complete pregnancy history is essential and should include the mother's age, number of pregnancies, number of deliveries, prenatal care, and number of induced and spontaneous abortions. The pregnancy history should be obtained with the intent of determining parameters that may present risks to the fetus, such as history of exposure to illness, maternal rash, maternal bleeding, maternal drug or alcohol use, and abnormal fetal growth. The history of labor and delivery is often a clue to the timing of a CNS injury. The examiner should note the type of anesthetic, if any, used for delivery of the child; duration of the rupture of membranes; whether or not there was meconium staining; fetal heart rate patterns if available; and finally, the child's Apgar scores. Gestational age should be noted, as this knowledge may impact interpretation of the newborn's neurologic examination.

Social History

The social history can provide clues to a neurologic diagnosis, such as exposures to toxins or medications. School reports may highlight specific cognitive difficulties that a child may have. The adverse effect of environmental risk factors, such as single parenthood, less than a high school education for one parent, limited parental contact, parental mental health concerns, and parental predilection for substance abuse, may be evident in the child's development.

Family History

Family history is important in many neurologic abnormalities. The presence of consanguinity, neurologic disorders, and systemic disease should be noted in family members. A family history of neonatal deaths is often a clue to metabolic disorders. A family history of seizures often points to the presence of one of the epilepsy syndromes. Neurocutaneous disorders are often inherited in an autosomal-dominant fashion, and family members should therefore be examined for neurocutaneous lesions, such as hypopigmentation and hyperpigmented macules, if a neurocutaneous disorder is suspected.

3.1.3 Physical Examination

CNS function depends upon normal function of all other body organs. Thus, abnormalities of other organ systems detected on examination are important. However, particular attention should be paid to abnormalities of hair, skin, teeth, and nails because they, like the brain, are of neuroectodermal origin and may reflect CNS lesions. For example, the pattern of hair growth reflects underlying brain development, so that the absence of a posterior hair whorl or the presence of multiple hair whorls suggests an abnormality in prenatal brain growth. Neurocutaneous abnormalities, such as café au lait spots, neurofibromas, and port wine stains, occur in several CNS disorders, such as tuberous sclerosis, neurofibromatosis, and Sturge-Weber syndrome, respectively. Therefore, the child's entire skin surface should be examined during the physical examination. Weight, height, and head circumference should routinely be measured. At birth, head circumference is approximately 35 cm, with growth at a rate of 2 cm per month from 0 to 3 months and 1 cm per month from 3 to 6 months of age. Intrauterine insults and many genetic syndromes associated with below- or above-average size have been linked with developmental delay. Microcephaly and macrocephaly are red flags for developmental problems with underlying structural CNS pathology, especially in the context of genetic or acquired disorders. As long as the head circumference is within normal limits, the size of the anterior fontanel is of little concern. Conditions that may lead to a large anterior fontanel include hypothyroidism, trisomy syndromes, in utero malnutrition, hypophosphatemia, rickets, osteogenesis imperfecta, and hydrocephalus.

3.2 Neurologic Examination of the Neonate

The formal neurologic evaluation includes an assessment of mental status, cranial nerves, motor system, sensory system, cerebellar function, and reflexes.

3.2.1 Mental Status Evaluation

The mental status examination of the neonate is made by the observation of spontaneous eye opening; movements of the eyes, face and extremities; and response to stimulation. Although both normal-term and preterm infants spend a large proportion of time in sleep, activity during wakefulness and duration of sleep vary with age. For instance, awake and sleep states are difficult to distinguish in a preterm infant born before 28 weeks of gestation. After 32 weeks of gestation, there is an increase in the frequency and duration of alertness. The normal-term newborn is easily aroused to a state in which the eyes are open and blink at a strong light stimulus. The ability to visually fix and follow at or after 34 weeks is a reassuring finding. To assess if a baby is visually fixing, the examiner should look for arrest of other activity, such as sucking. An astute examiner can observe subtle changes in mental status; an irritable infant will appear agitated, spontaneously cry, or cry to minimal stimulation and will not be easily soothed. The lethargic infant will have delayed or poorly maintained responses to stimulation.

3.2.2 Cranial Nerve Examination

Cranial Nerve I

Olfaction cannot be reliably assessed at bedside in the neonate.

Cranial Nerve II

Vision may be tested with the infant's blink response to a strong light stimulus. The blink response can be predictably elicited beyond 30 weeks of gestation. The ability of the infant to fix visually on a face and follow it is reassuring for the assessment of normal visual acuity. Visual fields are not reliably assessed in neonates. The pupillary response to light is predictably present beyond 29 weeks of gestation. Funduscopic examination may demonstrate the presence of congenital malformations involving the eye or retina. Placing a pacifier in the child's mouth may aid in keeping the eyes open during the examination. A direct and consensual pupillary response should be present. An afferent pupillary defect can be detected even at this young age by swinging the light from eye to eye and noting pupillary dilation when the light is brought to bear on the involved optic nerve.

Cranial Nerves III, IV, and VI

By 34 weeks of gestation, an infant will be able to fix and follow an object with his or her eyes, particularly the mother's face. Another maneuver to test extraocular movements is to stimulate the vestibulo-ocular reflexes by gently spinning the infant. The baby is held in front of and slightly above the examiner and spun to the right or left. There should be conjugate eye deviation in the direction in which the examiner spins the child. After cessation of spinning, post-rotational nystagmus in the opposite direction is noted for a brief period, after which the vestibular response is ablated by visual fixation. This technique allows the examiner to assess vestibular function, the presence of intact extraocular muscle function, and visual acuity with a single procedure. Of note, disconjugate gaze is common in normal newborn infants when they are not fixing on objects.

Fig. 3.1 (a) Congenital absence of the depressor anguli oris seen during smiling in early infancy. (b) Same patient as a toddler.

Cranial Nerve V

In neonates, the muscles of mastication can be assessed by watching the infant suck and swallow. The corneal reflex may be assessed at the end of the evaluation.

Cranial Nerve VII

Facial symmetry at rest and during sucking activity is used to assess facial nerve function. One should also note facial symmetry during crying. Congenital absence of the depressor anguli oris, a disorder that mimics facial nerve lesions, is noted only during smiling or crying (► Fig. 3.1a,b and ► Fig. 3.2).

Cranial Nerve VIII

The vestibular portion of cranial nerve VIII can be assessed by spinning the infant as described in the examination of cranial nerves III, IV, and VI. Hearing can be grossly evaluated by the presence of a blink elicited by a sharp sound, such as a bell directed at either ear. Vestibular function mediated by the vestibulocochlear nerves is tested by caloric stimulation. The head is angled at 30 degrees, orienting the horizontal semicircular canals vertically, and the external canal is inspected for cerumen or defects of the tympanic membrane. Ten milliliters of ice water is then instilled into the ear, and the resulting eye movements are observed. In the conscious patient, coarse nystagmus develops toward the ipsilateral ear

Fig. 3.2 Neonatal right peripheral facial palsy.

without eye deviation. In the comatose patient, the fast component is depressed, and the eye becomes tonically deviated ipsilaterally.

Cranial Nerves IX and X

The gag reflex can be reliably elicited beyond 30 weeks of gestation. The quality of the infant's cry may be abnormal in many neurologic as well as genetic disorders.

Cranial Nerve XI

Sternocleidomastoid function and trapezius function are best assessed in the neonate by detecting shoulder droop, by noting a preferential position of the infant’s head and decreased spontaneous activity of the shoulders, or both.

Cranial Nerve XII

Tongue movements of the normal newborn are such that fasciculations are difficult to recognize, but atrophy, tongue deviation, or both, can be appreciated.

3.2.3 Motor Examination

Normal newborn motor function varies with gestational age (► Table 3.1). From 28 to 40 weeks, with myelination of subcortical motor pathways from the brainstem, the infant develops increasing flexor tone in the legs, with increasing flexor tone spreading rostrally. After 40 weeks, with progressive myelination of the corticospinal tracts, there is a progressive “unfolding” from the flexor tone of the neonate to balanced flexor–extensor tone, increasing voluntary control of axial and extremity muscles, and refinement of movements in a rostral to caudal, proximal to distal fashion. The newborn motor examination is best achieved through the

observation of spontaneous motor activity, tone, and posture. Overall, the term infant’s movements are of small amplitude and rapid frequency, whereas those of a preterm infant are slow and athetoid in quality.

At 28 weeks of gestation, the normal posture of the preterm infant is flexion of the lower extremities with partial abduction at the hip and extension of the upper extremities. Abnormal postures, such as extension of the lower extremities in the term infant or flexion of the upper extremities in the premature infant, indicate hypertonia. Grasping the infant’s arms and pulling the infant to a sitting position allows examination of cervical tone. The normal preterm infant has profound head lag with little to no neck flexion. In contrast, the term infant has both extension and flexion of the neck if normal strength is present. Tone can also be assessed through the vertical and horizontal suspension maneuvers. In the vertical suspension maneuver, the infant is held under the axilla. The hypotonic infant will slip through the examiner’s hands. In the horizontal suspension maneuver, support is held under the trunk with the infant in the prone position. The normal infant can hold the head up and flex the limbs against gravity with the back held relatively straight. The hypotonic infant, when held in this position, will form a u-shape characteristic of hypotonia. Of note, because infants function primarily at the level of the rubrospinal, vestibulospinal, and reticulospinal pathways, they can have significant hemispheric dysfunction with relatively few deficits on the neurologic examination.

Table 3.1 Summary of the neurologic examination with respect to gestational age

	28 weeks	32 weeks	34 weeks	40 weeks	Red flags
Mental status	Needs gentle rousing to awaken	Opens eyes spontaneously; sleep–wake cycles apparent		At 36 weeks ↑ alertness, cries when awake	-Irritable or lethargic infant
Cranial nerves					
Pupils	Blinks to light	Consistent pupillary reflex	Fix and follow		-No response to auditory stimulus -“Chomp suck”: clamps down on pacifier but no suck (bulbar dysfunction)
Hearing	Pauses, no orientation to sound			Head + eyes turn to sound	
Suck + swallow	Weak suck, no synchrony with swallow	Stronger suck, better synchrony with swallow		Coordinated suck + swallow at 37 weeks	
Motor					
Posture	Minimally flexed	Flexed hips and knees	↑ Flexion at hips and knees	Flexed in all extremities	-Hypotonia -Hypertonia
Neck flexion	0	0	0	Fair	-28-Week infant with jerky movements -Full-term infant with writhing movements
Reflexes					
Moro reflex	Weak, incomplete hand opening	Complete extension + abduction		Full Moro reflex (with anterior flexion)	-Asymmetry -If obligatory or sustained, suggests pyramidal or extrapyramidal motor abnormality
ATNR	Present but weak	Present, involves arm		ATNR appears at 35 weeks	-Fixed obligate grasp (suggests bilateral hemispheric dysfunction.)
Palmar grasp	Present with reinforcement	Present without reinforcement	Grasp stronger	Strong grasp, able to be lifted out of bed	
Rooting			Present	Present	

Abbreviation: ATNR, asymmetric tonic neck reflex.

3.2.4 Sensory Examination

The full sensory examination assesses sensation to light touch, pinprick, temperature, vibration, and proprioception but is difficult to perform completely in neonates. Sensation can be grossly tested with pinprick and by observation of the neonate's response, either facial grimace or withdrawal of an extremity, to the stimulus beginning at 28 weeks of gestation. In an infant who is feeding, interruption of the sucking rhythm indicates perception of the sharp stimulus.

3.2.5 Reflexes

Beginning at 33 weeks of gestation, the Achilles, patellar, biceps, brachioradialis, and pectoral reflexes can be elicited. Myotactic reflexes are elicited with sudden tendon stretch by percussion over the tendon. The muscle itself should not be percussed, because muscle contraction occurs even in the presence of lower motor neuron lesions. The plantar response is a nociceptive reflex elicited by noxious stroking of the lateral aspect of the plantar surface from the heel toward the toes. This is not a helpful response to elicit in newborns as the response can be flexor or extensor, depending on the technique used to elicit the response. Unsustained clonus at the ankle (<8 beats) is normal if symmetrical, but sustained clonus is suspect at any age.

Primitive Reflexes

Several primitive reflexes evolve with maturation of the CNS and reflect the functional integrity of the brainstem. As a group, they tend to be symmetric, and they are modified with age, reflecting the normal maturation of descending inhibitory cerebral influences. Persistence of these reflexes indicates improper maturation of brain structures or injury (see ► Table 3.1).

The full Moro reflex consists of bilateral hand opening with upper extremity extension and abduction, followed by anterior flexion of the upper extremities, then an audible cry. This is best elicited by dropping the infant's head in relation to the body into the examiner's hands, but any sudden change in position will elicit this reflex. The Moro reflex, which is mediated by the vestibulospinal pathway, is fully elicited at 28 weeks of gestation and disappears at 4 to 6 months of age.

The asymmetric tonic neck reflex (ATNR) is elicited by rotating the head to one side, with subsequent elbow extension to the side toward which the head is turned and elbow flexion on the side of the occiput (► Fig. 3.3). This reflex also disappears at 4 to 6 months of age. An obligate ATNR is always abnormal and indicates bilateral hemispheric dysfunction with lack of brainstem inhibition of this reflex.

The palmar grasp, mediated by brainstem vestibular nuclei, is elicited by placing a finger in the palm. This results in flexion of the infant's hand, with flexion of the elbow and shoulders. Persistence of this response beyond 4 to 6 months is abnormal (see ► Table 3.1).

3.3 Neurologic Examination of the Infant

The neurologic examination of the child beyond the newborn period can be challenging, especially as stranger anxiety peaks

Fig. 3.3 Asymmetric tonic neck reflex.

between 18 and 24 months of age. However, stranger anxiety is a normal phenomenon, and its presence signals cognitive development. There are various approaches to examining children in this age range. As a rule, the direct approach of examining a child starting with the head and finishing with the feet is doomed to failure. On the other hand, observation of the child interacting with toys or family members allows the examiner to glean much of the information needed about the child's neurologic status. Invasive aspects of the examination, such as the fundoscopic examination, are performed last. In our experience, more information is obtained from observation of a child than from auscultation, palpation, percussion, testing of reflexes, sensory testing, and ophthalmologic examination.

3.3.1 Mental Status Evaluation

The evaluation of mental status in the infant is, as in the neonate, performed by observation of spontaneous activities, feeding behavior, and interaction with the environment. Language can be assessed as well by noting the use of gestures, such as pointing or shaking the head to indicate wants.

3.3.2 Cranial Nerve Examination Cranial Nerve I

Once the child has developed speech, olfactory function can be tested. Oils such as clove and peppermint can be used to assess

perception of smell. Highly volatile substances, such as ammonia, should not be used because they are irritating and test cranial nerve V function at the level of the nasal mucosa rather than olfaction.

Cranial Nerve II

By 6 months of age, visual acuity has been found to be 20/20 by visual evoked potentials. During the examination, visual acuity can be estimated to be grossly normal if the infant can visually locate and track a small object. Peripheral vision can be tested by bringing an object into the visual field from behind the child.

Cranial Nerves III, IV, and VI

In the older infant and child, extraocular movements can be easily assessed by having the infant visually follow an object of interest. The third nerve innervates the medial rectus, superior and inferior rectus, inferior oblique, and levator muscles of the upper eyelid and supplies the parasympathetic constrictor fibers to the pupil. A parasympathetic lesion results in pupillary dilatation, whereas a sympathetic lesion results in a small, myotic pupil. The fourth cranial (trochlear) nerve innervates the superior oblique muscle, which depresses and intorts the eye. Weakness of this muscle results in head tilt to the opposite shoulder as compensation for the lack of intorsion. The sixth cranial nerve innervates the lateral rectus muscle, which abducts the eye. Abnormalities of cranial nerves III, IV, or VI may cause diplopia. In the infant, this may cause such subtle signs as irritability or may be overtly manifest in the child who covers an eye to view objects.

Supranuclear lesions involving the corticobulbar pathways that innervate the third, fourth, and sixth nerve nuclei result in abnormalities of volitional gaze. Pursuit movements are intact, but saccadic movements are severely impaired. The patient cannot volitionally change eye direction and must use vestibulo-ocular reflexes to move the eyes. Children with these abnormalities close their eyes to break fixation and turn the head in the direction opposite that toward which eye movement is desired. Once the object of interest enters the visual field, the child opens the eyes, fixes on the object, and then uses pursuit movements to bring the object into binocular fixation. The disorder is known as oculomotor apraxia. Intranuclear ophthalmoplegia, in which there is paresis of the adducting eye and nystagmus of the abducting eye, is due to lesions of the medial longitudinal fasciculus. Paralysis of upward gaze is seen in lesions of the periaqueductal gray matter.

In the infant, deviation of the eye may be observed. Misalignment of the visual axes is referred to as strabismus and may be secondary to phoria or a tropia. Phorias are held latent by sensory fusion but can be elicited with the cover-uncover test. When an infant uses binocular vision to fix on an object, the phoria disappears. When one eye is covered, however, the eye seeks a position at rest and deviates from the axis of the other eye. When the eye is uncovered and binocular vision is reestablished, the eyes realign. The slight movement of the eye indicates that a phoria is present. Tropias are deviations of the eye noted at rest that cannot be overcome by fusion. Both phorias and tropias are further defined according to the direction of deviation with the prefix *eso-* (if the eye turns inward) or *exo-*

(if the eye turns outward). If the eye movements are full and conjugate, the strabismus is nonparalytic and indicates that a supranuclear gaze abnormality is present. On the other hand, if there is limitation of eye movement, the strabismus is paralytic and indicates a nuclear or infranuclear lesion.

Cranial Nerve V

The masseter muscles can be palpated, and jaw deviation can be assessed by simple observation. The trigeminal nerve additionally can be assessed by testing sensation with a cotton wisp over the face in the distribution of the V₁, V₂, and V₃ branches of the trigeminal nerve.

Cranial Nerve VII

Symmetry of facial movement in the examination of infants of this age can be assessed both at rest and during smiling, crying, or grimacing. Taste testing is reliable.

Cranial Nerve VIII

The infant begins to localize sound at 4 months.

Cranial Nerves IX and X

The gag reflex is easily assessed at the end of the examination.

Cranial Nerve XI

As in the newborn, shoulder droop or head tilt is indicative of dysfunction of the sternocleidomastoid and trapezius muscles.

Cranial Nerve XII

In the infant, fasciculations, tongue atrophy, and tongue deviation can be assessed. Specific tongue movements can be assessed at 1 year of age by having the child follow a tongue depressor with the tongue.

3.3.3 Motor Examination

Tone and Posture

The best way to examine the infant is by observation of the infant lying quietly on the examination table. The presence of unusual posturing of the limbs may indicate basal ganglia lesions. Tone and passive range of motion of the extremities will provide information regarding spasticity and rigidity. Spasticity is characterized by a “clasp knife” response, with resistance to passive stretch and sudden release at a critical point. Resistance to passive stretch is encountered through the entire arc in rigidity. Assessment of the infant’s posture is very age-dependent. The child is able to lift the head off the examination table at 2 months of age and lift both head and chest off the table at 3 months of age. Crawling is seen at 9 to 12 months of age. The child can reach at 4 to 5 months of age, and most infants can sit unsupported at 7 months. At 12 to 15 months of age, the child can walk independently, but the gait is broad-based and unsteady. The base narrows to a few inches at 6 years.

Assessment of Muscle Bulk

Bulk is assessed by palpation, observation, and comparison with the contralateral limb. Atrophy can eventually occur with extrapyramidal and pyramidal lesions but is most pronounced with lower motor neuron lesions.

Assessment of Muscle Strength

Quantitative assessment of muscle strength is difficult in this age group. A few maneuvers in the examination can help the examiner assess the infant's strength. By holding the infant in the axilla and noting the resistance in the trunk when lifting the child, the examiner can assess upper extremity strength. To test lower extremity strength, the examiner can note whether the infant can bear weight on the legs if supported. However, strength is best evaluated by observation of the child's functional activity. For example, arm and shoulder strength can be assessed by observing the infant in the prone position and the ability to raise the head off the examination table by pushing with the arms. Muscle weakness of pyramidal origin is spastic, whereas extrapyramidal weakness is rigid. Flaccidity is seen with lower motor neuron disease. The development of a definite hand preference before 24 months of age suggests that a lesion is present in the CNS or the peripheral nerves of the opposite limb. Fine motor development is indicated by the appearance of a pincer grasp at the age of 9 months (► Fig. 3.4).

3.3.4 Cerebellar Examination

Gait should also be tested in those children who are ambulatory, but the examiner should remember that gait varies with the child's age. Gait progressively narrows during early childhood. Formal cerebellar testing is difficult in the infant, as it requires some playful interaction between the examiner and the infant. Observation of the infant sitting alone may be helpful, as truncal sway may indicate cerebellar dysfunction. Titubation of the head may also be present. Fine motor coordination can be tested by having the child reach for objects and noting signs of tremor or dysmetria.

Fig. 3.4 A pincer grasp in a normal 9-month-old infant.

3.3.5 Sensory Examination

Sensory testing in this age group must be performed with care. The infant usually responds to light touch by looking at the stimulus source and withdrawing the extremity. A vibratory stimulus is perceived by most infants as a startle and is quite different from touch. Proprioception cannot be directly evaluated, but posture and gait are often clues to abnormalities of proprioception. Pain sensation can be assessed by using a pin, but this should be performed late in the examination, and the pin should be hidden from the child. If the child sees the pin early in the process, any productive interaction between examiner and patient will be lost.

3.3.6 Primitive Reflexes

The primitive reflexes were described in the discussion of the neonate. As previously noted, of particular importance in this age group is documentation of the appearance and disappearance of these primitive reflexes, as they reflect the maturation of the CNS (see ► Table 3.1). For instance, the plantar grasp, which appears at birth, usually disappears by age 9 to 10 months. The continued presence of this response interferes with the progression to weight bearing on the legs and ultimately walking. The ATNR should not persist beyond 6 months of age. Persistence of this response interferes with sitting or standing.

Failure to develop certain responses also indicates that abnormalities are present. The parachute response appears after 6 to 8 months of age and is mediated by the brainstem vestibular nuclei. This response persists throughout life in modified forms. It can be tested by tilting a sitting infant to either side, which results in extension of the ipsilateral arm in a protective fashion (► Fig. 3.5). The response can also be elicited by picking up the infant and thrusting the infant's head toward the examining surface, with resultant bilateral extension of both upper extremities. A child who does not exhibit a parachute response is unlikely to walk in the near future, and failure to develop a parachute response can be a predictor of whether a child will develop the ability to walk.

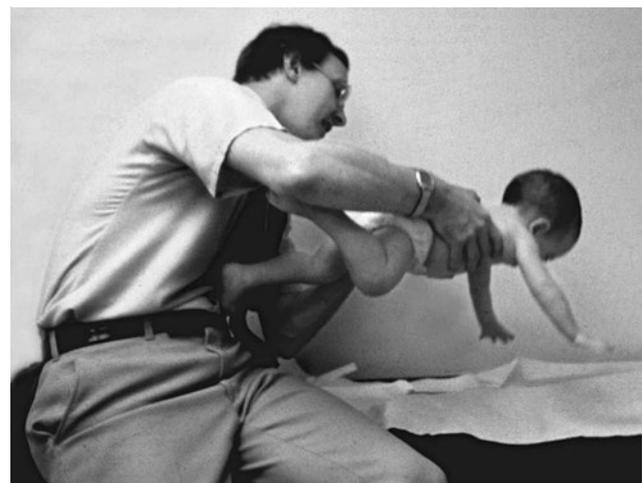

Fig. 3.5 The parachute response in a normal 9-month-old infant.

3.4 Examination of the Older Child

3.4.1 Mental Status Evaluation

In the older child, language can be specifically tested, including speech, reading, and writing. Dysarthria refers to abnormalities of the speech mechanism, which is mediated by the hypoglossal, vagus, facial, and trigeminal nerves. Receptive aphasia refers to impairment of language comprehension and reception, occurring with lesions in the posterior superior temporal lobe gyrus in the Wernicke area. Impairment of speech production and fluency results in expressive aphasia, which occurs with lesions of the posterior inferior frontal lobe gyrus, or Broca area. Conduction aphasia results in the ability to repeat but not to name objects. This occurs with lesions of the arcuate fasciculus, which connects the Broca and Wernicke areas. Calculation is a dominant-hemisphere function residing in the angular gyrus. In a child about the age of 7 years, calculations can be assessed by asking the child to subtract numbers. The nondominant hemisphere can be tested by using picture drawings to assess visual spatial function. Memory can be tested beginning at 4 to 5 years of age, when a child is able to remember four digits. The normal adult can remember seven or eight digits.

3.4.2 Cranial Nerve Examination

Cranial Nerve I

Each nostril is tested individually with occlusion of the contralateral nostril. The child is asked to name the perceived smell. This test is best performed at the age of 6 years, as the child is sufficiently verbal then to comply with the examination.

Cranial Nerve II

Examination of the optic nerve can be divided into visual acuity, funduscopic examination, and visual fields. By the age of 4 years, a child can cooperate well enough to use a visual acuity chart. Visual fields can be evaluated with a white or red test object or with double simultaneous stimulation in both visual fields.

Cranial Nerves III, IV, and VI

The oculomotor, trochlear, and abducens nerves are examined in much the same way as they are in infants and neonates.

Cranial Nerve V

In the older child, the sensory distributions of V_1 , V_2 , and V_3 can be accurately delineated. The trigeminal nerve is tested by noting jaw deviation and palpating the masseter muscles.

Cranial Nerve VII

The motor function of the facial nerve is assessed as described above. In addition, taste sensation over the anterior two-thirds of the tongue can be tested after the age of 6 years with salt and sugar sensations. However, it is important to be certain that the

patient is able to identify whether or not the test solution is salt or sugar. Once the tongue is back in the mouth, the solution is spread to the distribution of the contralateral seventh nerve, as well as of the ninth and tenth cranial nerves posteriorly.

Cranial Nerve VIII

The auditory component of the vestibulocochlear nerve, hearing, can be tested in the older child with a whisper. The best technique is to use spondee words—that is, words with equally accented syllables or one syllable, such as “cowboy” and “night-light.” These words are whispered at a distance of 2 feet while the opposite ear is masked. Vestibular function mediated by the vestibulocochlear nerve is tested by caloric stimulation as previously described

Cranial Nerves IX and X

The gag reflex is tested as described in the infant.

Cranial Nerve XI

In the older child, a shoulder droop or a head turning may be detected with lesions of cranial nerve XI. The upper fibers of the trapezius can be palpated as the child attempts to elevate the outstretched arms against resistance. The sternocleidomastoid muscle is palpated as the child attempts to turn the neck against resistance.

Cranial Nerve XII

In the older and cooperative child, fasciculations and atrophy are more easily appreciated. In children with a lower motor neuron lesion of the hypoglossal nerve, the tongue deviates in the direction of involvement of the hypoglossal nerve or nucleus, and in an upper motor neuron lesion, it deviates in the direction opposite that of cerebral hemispheric involvement.

3.4.3 Motor Examination

Assessment of mass, strength, and tone comprises the motor evaluation of the older child. Strength is tested as resistance against passive movement by the examiner and, in the older child, can be assessed quantitatively. It is traditionally graded from 0 to 5. A grade of 0 indicates no movement, 1 indicates a flicker of movement, 2 indicates movement with gravity eliminated, 3 indicates the ability to move against gravity but minimal resistance, 4 indicates the ability to move against some resistance, and 5 indicates normal power. Innervation of specific muscles is listed in ► Table 3.2 and ► Table 3.3.

3.4.4 Cerebellar Examination

The child should be observed standing, starting to walk, stopping, and turning, along with the associated limb movements. These movements require the coordination of sensory, motor, cerebellar, visual, and vestibular functions. For example, a wide-based gait may be seen with disorders of the neuromuscular junctions, peripheral nerves, and muscles because of weakness. Therefore, observation of a wide-based gait should

prompt a work-up, not only for cerebellar disease but also for other lesions that may affect the gait. Rapid alternating movements should also be tested as a part of the cerebellar examination. In cerebellar disease, the rate, amplitude, direction, and strength will be diminished. Abnormalities in performing rapid alternating movements may also be seen in extrapyramidal disease, with diminished rate and amplitude, and in corticospinal disease, with diminishing amplitude of successive movements. Dysmetria, an error in measuring distances, may be noted, as well as intention tremor during finger-to-nose or heel-to-knee-to-shin movements.

3.4.5 Sensory Examination

The full sensory examination assesses sensation to light touch, pinprick, temperature, vibration, and proprioception. Cooperation is essential in assessing sensory function in children. The examination should not be relied upon if there is any doubt as to the child's cooperation. In most children beyond the age of 6 years, a useful screening sensory examination of the hands can be performed by asking the child to distinguish between coins, particularly a penny and a dime. If these functions are intact, it

assures the examiner that the peripheral receptors, peripheral nerves, dorsal root ganglia, spinal cord pathways, and thalamic and parietal cortical sensory systems are intact. If abnormalities are suggested in this task, then the examiner must perform detailed testing of individual sensory modalities. Segmental sensory innervations are mapped according to a dermatomal chart (► Fig. 3.6, ► Fig. 3.7, ► Fig. 3.8, ► Fig. 3.9). If all sensory pathways are intact but the patient is unable to identify objects presented, astereognosis is present, indicating a lesion of the parietal lobe.

3.4.6 Reflexes

Reflexes are graded from 0 to 4+, with absence of a reflex recorded as 0 and normal reflexes as 2+. If clonus is elicited, reflexes should be graded as 4+. Reflexes may be involuntarily diminished by muscle contraction, so distraction techniques should be used when this is suspected. After the age of 2 years, the plantar response is consistently flexor. The extensor, or Babinski, response is characterized by extension of the great toe and fanning of the other four plantar digits and is a sign of corticospinal tract lesions.

3.5 Editor's Comments

This chapter is one of the most important in the entire book. It is incumbent on pediatric neurosurgeons to distinguish normal

from abnormal development, to know that several beats of ankle clonus in a newborn are normal but that the development of handedness in a 2-year-old is abnormal. The authors note that a careful neurologic examination of an infant or child may avoid unnecessary tests; that is true, but more importantly, it gives information about the function of a child's immature nervous system, information that aids the interpretation of neuroimaging.

Pearls

- More information is obtained from observation of a child than from auscultation, palpation, percussion, testing of reflexes, sensory testing, and ophthalmologic examination.
- Stranger anxiety in the toddler makes for a difficult examination but is an indicator of cognitive development.
- Knowledge of normal developmental milestones is essential to interpretation of the neurologic examination.
- Hand preference before the age of 2 years is abnormal.
- A child who does not exhibit a parachute response is unlikely to walk in the near future.

4 Caring for the Pediatric Neurosurgical Patient

Stephanie Greene

The care of pediatric neurosurgical patients is a broad and challenging topic. This chapter deals principally with general guidelines for the management of these children, from measures to reduce infection to pain control regimens to efforts to limit postoperative complications. Specific topics are addressed in considerably more detail in individual chapters.

4.1 Preoperative and Perioperative Management

4.1.1 Patient Preparation for Surgery

Patients at Children's Hospital of Pittsburgh are requested to use a chlorhexidine gluconate shampoo and body wash (4% w/v chlorhexidine gluconate; Hibiclens) for five consecutive nights leading up to the surgical date for all elective procedures. Although the Cochrane Database guidelines do not recommend preoperative body washing to reduce surgical site infections (SSIs; commonly used abbreviations are listed in ► Table 4.1), those guidelines are based on data from 20 to 30 years ago.¹ Multiple studies with sample sizes too small to achieve statistical significance have found lower numbers of colony-forming units (CFUs) on the incisions, on the intraoperative cultures, and on the skin of patients who showered preoperatively with chlorhexidine gluconate.²⁻⁵ Multiple days of showering have been recommended, with the most important day being the day before surgery.^{6,7} The preoperative skin preparation should be the same preparation used in the operating room (OR) immediately before surgery, as the effect of exposure to a skin preparatory product is cumulative.⁸

Hair clipping should be minimal and should be performed just before skin preparation in the OR. Clipping hair in the days before surgery may lead to an increased incidence of infection, although data have not been statistically significant.^{9,10} Shaving should not be performed, as infection rates are clearly higher.^{9,11,12} The avoidance of hair clipping is associated with a slightly lower rate of postoperative infection, and some have suggested that no hair removal be performed.¹³⁻¹⁵

Skin preparation before incision is not performed in a uniform fashion around the country. Chlorhexidine gluconate (2% chlorhexidine gluconate, 70% isopropyl alcohol) achieves greater reduction of skin microflora than does povidone-iodine and has greater residual activity after a single application.^{2,16,17} Ethanol produces faster bactericidal activity, and at high concentrations it is the most effective product against viruses. However, its flammability makes it a less desirable option in the OR.¹⁸ Preoperative skin antisepsis with chlorhexidine-alcohol was shown to be superior to povidone-iodine in reducing SSIs, both superficial and deep.¹⁹ Chlorhexidine acts by disrupting cell membranes and carries a risk for ototoxicity. Povidone-iodine acts by oxidizing amino acids and disrupting cell membranes. Because iodine can produce hypothyroidism in low-birth-weight infants, its use should be limited accordingly.^{20,21} Alcohol acts by denaturing proteins. Iodine has the lowest risk for complications, and alcohol has the shortest duration of

action. Alcohol-based solutions should be avoided in neonates before of the possibility of burns.²² Chlorhexidine gluconate is recommended for use in children past the age of 2 months by the manufacturer for this reason.

4.1.2 Preoperative Medication Management

For elective neurosurgical patients, anticoagulation should nearly always be discontinued before surgery. Aspirin can be administered no more than 7 days before surgery without an adverse effect on coagulation, although aspirin may be intentionally continued through surgery in selected patients

(e.g., those with moyamoya). Nonsteroidal anti-inflammatory drugs (ibuprofen, naproxen; medication dosages are listed in ► Table 4.2) should not be administered during the 24 hours before surgery. Patients on warfarin should be transitioned to heparin in the hospital with the consultation of the hematologist, or to low-molecular-weight heparin (enoxaparin [Lovenox] or dalteparin [Fragmin]) 3 days before the procedure. Low-molecular-weight heparin should be discontinued 24 hours before the procedure, and heparin 6 hours before the procedure. Clopidogrel (Plavix) must be stopped 5 to 7 days before surgery. The reason that the patient is taking the anticoagulant must be weighed against the risk for intraoperative and postoperative bleeding.

Antibiotics are administered within 1 hour of surgery for every case, with the possible exception of cases in which identification of a microorganism is desired. The usual choice of antibiotic is cefazolin, although clindamycin and vancomycin are second-line substitutes for those with a cephalosporin allergy. Antibiotic prophylaxis has been shown to be generally effective in reducing the risk for wound infection in a wide variety of adult cases.²³ Prophylactic antibiotic therapy has been shown to be effective for craniotomy and spinal surgery in adults, although no role for prophylaxis against gram-negative organisms or multiple doses of antibiotics could be proven effective.^{24,25} Prophylactic antibiotics reduce the risk for meningitis by approximately 50% in adult patients undergoing craniotomy.²⁶ A single dose has been shown to be adequate for surgical wound prophylaxis in many cases, including gastrointestinal surgery cases.²⁷ Repeat dosing while the patient remains in the OR is recommended to maintain adequate serum levels during surgery.²⁸ Studies have demonstrated the efficacy of intraoperative dosing of antibiotics in reducing postoperative incisional infections, although not postoperative meningitis.^{29,30} Additional dosing beyond the termination of surgery is not generally recommended.²⁸ However, the use of 24 hours of prophylactic antibiotics in patients undergoing implantation of shunts was found in a meta-analysis to reduce the rate of shunt infection.³¹ Dosing for more than 24 hours postoperatively in any case is not recommended.²⁸

The use of local anesthetic has several advantages. Long-lasting anesthetics like bupivacaine allow improved postoperative pain control, with a reduction in the need for opioid administration. The addition of epinephrine to the local anesthetic prolongs the duration of the anesthetic effect; it also produces vasoconstriction, thereby reducing blood loss during skin opening. This is especially desirable in neonates, in whom little blood loss is tolerated. The use of local anesthetic must be meticulously avoided in patients undergoing extracranial–intracranial bypass, to avoid both vasoconstriction and inadvertent injury to the donor vessel.

4.1.3 Infection Control Measures

Hand washing by surgical personnel is a variable process among institutions and individual surgeons. Chlorhexidine gluconate is clearly superior to povidone–iodine in terms of reducing the number of CFUs that surgical personnel have on their hands after performance of routine preoperative hand antisepsis. No effect of the length of time a scrub is performed has been demonstrated, although 2 minutes appears to be the minimum

necessary.³² Hand rubbing with an aqueous alcohol-based solution, preceded by a 1-minute nonantiseptic hand wash before the surgeon's first case of the day or when hands are overtly soiled, is as effective as traditional hand scrubbing with antiseptic soap in preventing SSIs.³³ The use of an alcohol-based chlorhexidine surgical rub (1% chlorhexidine gluconate and 61% ethyl alcohol w/w [Avagard; 3 M, St. Paul, MN]) instead of a traditional aqueous chlorhexidine scrub may be more effective in reducing the bacterial flora on the hands in both an immediate and a delayed fashion.³⁴ Multiple studies demonstrating a reduced number of CFUs on the hands with the use of chlorhexidine have been performed, but none has linked the use of any preoperative hand scrub or surgical site preparatory solution to a decreased incidence of SSIs.

Double gloving has been resisted by many surgeons because of reduced tactile sensation and increased cost. Nonetheless, bacterial migration through punctures in surgical gloves has been shown to occur.^{35,36} Double gloving has been shown to reduce the likelihood of blood-borne pathogen transmission, and some studies have suggested that it reduces the risk for SSIs.³⁷ This is a simple measure to reduce the incidence of infection for the patient and the surgical team and should be carried out routinely.

It has been suggested that the outer gloves be changed before shunt components are handled, and several studies have documented a decrease in the incidence of shunt infection when this is done.^{38,39} Bacteria are present on the outer gloves within 15 minutes of the initiation of surgery³⁸; changing the outer gloves after a period of time, or before handling implants, is reasonable. The use of a no-touch technique has been advocated by many pediatric neurosurgeons, but a recent study from the Hydrocephalus Clinical Research Network did not demonstrate a statistically significant decrease in infection when a no-touch technique was used.⁴⁰

Antibiotic-impregnated shunt catheters are available for use as external ventricular drains (EVDs) or ventriculoperitoneal shunts. The catheters are impregnated with rifampin and clindamycin (Bactiseal; DePuy, Warsaw, IN; Ares; Medtronic Neurosurgical, Goleta, CA) or with minocycline and rifampin (Ventriclear; Medtronic); no difference in infection rates has been identified between the two catheter types for external ventricular drains.⁴¹ One study of adult neurosurgical patients found that the use of antibiotic-impregnated EVDs was as effective as the use of systemic antibiotics in preventing cerebrospinal fluid (CSF) infection.⁴² Other studies have found a clear reduction in EVD infections with the use of antibiotic-impregnated catheters and have recommended their routine use.^{43,44} The use of prophylactic systemic antibiotics while an EVD is in place has been found to reduce the incidence of infection in multiple studies.⁴⁴ The use of antibiotic-impregnated shunt catheters may provide a reduction in shunt infection.³¹ A multicenter research initiative under way through the Hydrocephalus Clinical Research Network aims to identify factors that reliably decrease the incidence of shunt infections. The use of antibiotic-impregnated shunt catheters is one of the factors being investigated at present.

Skin closure is largely a matter of surgeon preference. Staples, nylon sutures, and absorbable sutures are options. There is a significant advantage to not having to remove sutures or staples in combative or fearful children. The use of staples may

Naproxen (Aleve; Bayer, Pittsburgh, PA; Naprosyn; Roche)	PO: children > 2 years: 5–7 mg/kg/dose every 8–12 hours; maximum 1,000 mg/day
Nicardipine (Cardene; EKR Therapeutics, Bedminster, NJ)	IV: 0.5–1 µg/kg/min via continuous infusion, titrating to goal blood pressure with increases every 15–30 minutes; maximum dose 4–5 µg/kg/min
3% Normal saline	3–10 mL/kg as a bolus dose, or a continuous infusion beginning at 1 mL/kg/h and increased to effect, maintaining serum osmolality < 360 mOsm/L
Oxycodone (OxyIR; Roxicodone; Xanodyne, Newport, KY)	PO: 0.05–0.1 mg/kg/dose every 3 hours as needed; escalate as needed to 0.15 mg/kg/dose; begin at 5–10 mg/dose in adolescents > 50 kg
Phenobarbital	IV loading dose: 10–20 mg/kg; maximum 30–40 mg/kg IV/PO maintenance dose: Neonates: 3–4 mg/kg/day in 1–2 doses, increase to 5 mg/kg/day if needed Infants: 5–6 mg/kg/day in 1–2 doses Children 1–5 years: 6–8 mg/kg/day in 1–2 doses Children 5–12 years: 4–6 mg/kg/day in 1–2 doses Children > 12 years: 1–3 mg/kg/day in 2 doses
Phenytoin	IV: Loading dose: 15–20 mg/kg Maintenance dose: begin at 5 mg/kg/day divided into 3 doses, may increase to 10 mg/kg/day
Polyethylene glycol (MiraLax; MSD Consumer Care, Summit, NJ; GlycoLax; Kremers Urban, Seymour, IN)	PO: 0.5–1.5 g/kg/day, not to exceed 34 g/day; titrate to goal of two soft stools per day
Sucrose	
Vancomycin	IV: Children 1 month–12 years: 15 mg/kg/dose every 6 hours Children > 12 years: 15 mg/kg/dose every 8 hours; maximum 2,000 mg/dose

Note: All dosages should be confirmed with the hospital pharmacist before administration.

be associated with a lower risk for infection than the use of suture, but staples are also associated with increased pain.⁴⁵ Some surgeons apply an antibiotic ointment, such as bacitracin (X-Gen Pharmaceuticals, Big Flats, NY) or Neosporin (neomycin sulfate, polymyxin B, and bacitracin zinc; Johnson & Johnson, New Brunswick, NJ), over the suture line before applying a dressing. Others use petrolatum gauze (Xeroform; Covidien, Mansfield, MA). Dressings range from 2-octyl cyanoacrylate (Dermabond; Ethicon, Somerville, NJ), to Telfa (Kendall [Covidien]) secured with paper tape or a clear occlusive dressing (Tegaderm; 3M), to full head wraps with bandage roll, such

as Kerlix (Covidien) and Kling (Johnson & Johnson). Dressings are typically left in place for 24 to 48 hours. There is no advantage to leaving dressings in place longer, or in replacing them, over conventionally closed incisions. Some argue that dressings are unnecessary.^{46,47} The need to keep a child's hands away from the incision frequently mandates a dressing, however. The application of tissue adhesives, such as Dermabond, in addition to sutures may provide a lower risk for infection than suture or staples alone, although tissue adhesives should not be used independently for primary wound closure, as the risk of dehiscence is unacceptably high.^{48,49} One small study demonstrated

a lower rate of shunt infection with the use of subcuticular sutures and Dermbond than with conventional nonabsorbable skin sutures.⁵⁰

The use of antibiotic-coated suture has become popular over the last ten years. Triclosan-coated polyglactin 910 (Vicryl Plus, Ethicon) and poliglecaprone 25 with triclosan (Monocryl Plus, Ethicon) are the most popular choices. There are approximately as many studies concluding that the use of antibiotic-coated suture reduces the incidence of SSIs as there are that the use of antibiotic-coated suture has no impact on the incidence of SSIs.⁵¹⁻⁵⁴ The cost of antibiotic-coated suture is approximately 50% higher than the cost of standard suture,⁵⁵ so consideration of its use should not be taken lightly. The use of antimicrobial suture for wound closure resulted in lower infection rates in 61 patients undergoing 84 ventriculoperitoneal shunt surgeries in a prospective, randomized, double-blinded controlled trial.⁵⁶

4.1.4 Fluid and Electrolyte Management

Healthy children readily tolerate the absence of oral intake overnight. Standard preoperative instructions include nothing by mouth for 8 hours before surgery, with the following exceptions. Breast milk is allowed until 4 hours before surgery, and formula until 6 hours before surgery. Clear liquids, such as water, apple juice, Pedialyte (Abbott Nutrition; Columbus, OH), and Gatorade (Pepsico, Purchase, NY), are allowed until 2 hours before surgery. Medications normally taken in the morning are to be taken more than 2 hours before surgery with a sip of water. Certain medical conditions, such as moyamoya syndrome and diabetes insipidus, mandate that a patient be admitted to the hospital preoperatively for intravenous (IV) hydration overnight. These recommendations are based on the desire to limit both surgical and anesthetic complications associated with the procedure.

In general, hospitalized children beyond the neonatal period do best with 0.45% normal saline ($\frac{1}{2}$ NS) or more concentrated solutions, although there are reports of hyponatremia even with $\frac{1}{2}$ NS.⁵⁷⁻⁵⁹ Perioperative patients are more likely to develop hyponatremia than nonsurgical patients.⁶⁰ Neonates have higher water needs per kilogram and usually require D10 $\frac{1}{4}$ NS. Infants become dehydrated faster than older patients because of their higher body surface area. The use of isotonic fluids like NS or lactated Ringer solution (LR) is increasingly prevalent, as it avoids hyponatremia and prevents the hemolysis that results from hypotonic solutions. $\frac{1}{4}$ NS (osmolality 77) should not be administered peripherally, but D5 $\frac{1}{4}$ NS (osmolality 355) can be. Moderately hypertonic solutions are not problematic.

Daily maintenance IV fluid requirements are calculated as follows: 100 mL/kg for the first 10 kg, 50 mL/kg for the second 10 kg, and 20 mL/kg thereafter, with an upper limit of 2,400 mL/d. Sensible fluid losses, those that can be measured, including those from urine, stool, and nasogastric tube output, as well as surgical wounds, should be replaced. Insensible losses of water include water lost in perspiration and respiration, and these must be estimated. Exhaled air contains nearly 100% humidity. Maintenance fluids need to be adjusted for circumstances in which insensible losses (normally one-third of water loss) are increased, such as fever, the use of radiant warmers for premature infants (who may require 120 to 180 mL/kg/d), emesis or nasogastric suction, or the use of nonhumidified mechanical

ventilation. In general, the larger the incision, the larger the amount of intraoperative sensible fluid loss. And the smaller the patient, the larger the insensible losses because of the relatively large surface area of the skin.

The addition of dextrose to IV fluids is often avoided unless a patient's status is nothing by mouth (NPO) for a prolonged period of time or hypoglycemia (glucose < 70 mg/dL) is identified on blood testing. There is strong evidence that hyperglycemia increases the extent of infarction after stroke, so hyperglycemia is avoided to protect the vulnerable margins of a cortical resection. Hyperglycemia is also avoided for 24 to 48 hours following severe closed head injury, as several studies have demonstrated poorer outcomes in patients who were hyperglycemic on admission or during their hospitalization.^{61,62} Even a single dose of dexamethasone during the course of a craniotomy significantly elevates the serum glucose level and should be avoided in patients for whom hyperglycemia could be detrimental.⁶³

Hypoglycemia, however, particularly in neonates, entails its own set of problems and must be avoided as well. Whereas adults are able to maintain near-normal blood glucose levels for days, healthy neonates and young children become hypoglycemic after 24 to 48 hours. The glycogen stores of young children are adequate to maintain the serum glucose for no more than 5 to 10 hours. Because of the small muscle mass of children, oxidative metabolism of fatty acids occurs early, along with ketone body production. The relatively increased glucose requirements in children frequently result in hypoglycemia. The glucose in maintenance IV fluid is sufficient to provide approximately 20% of a patient's caloric needs, preventing ketoacidosis, but allows the loss of 0.5 to 1% of their weight each day. Neonatal hypoglycemia may be manifested by cyanosis, apnea, hypothermia, hypotonia, lethargy, or seizures. Consideration should be given to adding dextrose to IV fluid in neonates if enteral feeds are not expected to commence within 2 to 3 hours of surgery. Neonates require a glucose infusion rate of at least 6 to 8 mg/kg/min, which will usually be adequately supplied with a solution of D10 $\frac{1}{4}$ NS for term babies, with a goal serum glucose level above 60 mg/dL. Serum glucose levels should be closely monitored in patients who are NPO and not receiving dextrose in their IV fluids.

Intraoperatively, IV fluid management depends upon the goals of the surgery and estimated losses. Hyponatremia is meticulously avoided in all cases. Patients with brain tumors are maintained slightly hypovolemic, often with the assistance of mannitol, 3% NS, or furosemide (Lasix; Sanofi, Bridgewater, NJ), to minimize vasogenic edema of the tissue surrounding the tumor and to minimize the degree of retraction necessary to visualize and resect the tumor. In contrast, patients with moyamoya are aggressively hydrated, as their impaired cerebrovascular autoregulation limits their ability to adapt to hypovolemia without the risk for cerebral infarction. LR is routinely used as replacement for CSF in patients undergoing intraventricular endoscopy; this limits the incidence of mutism, which can develop postoperatively in these patients for reasons that are not understood.^{64,65} Patients enter the OR with a fluid deficit from being NPO for a number of hours before surgery. This is calculated as the maintenance IV fluid requirement multiplied by the number of hours the patient has been NPO, and the deficit is generally replaced in the first 2 to 3 hours of surgery. If the surgery lasts less than 2 hours, fluids can be replaced more rapidly and often are at the start of surgery because of relative

hypotension in the dehydrated patient, although rapid replacement of fluid can be very undesirable in patients undergoing craniotomy and must be discussed with the anesthesiologist before the start of the case.

Fluid replacement in the OR includes crystalloid, colloid, and blood products. The SAFE Study indicated that colloid replacement in patients with a disrupted blood–brain barrier (secondary to traumatic brain injury) was associated with higher mortality, so colloid (e.g., albumin) is almost never used in neurosurgical patients.⁶⁶ A neurosurgical patient's hemoglobin level is generally maintained at about 9 to 10 g/dL intraoperatively. Transfusion above a hemoglobin level of 8 g/dL has not been shown to lead to better outcomes, with the exception of patients with acute myocardial ischemia.⁶⁷ In selected patients with vascular or cardiac issues, transfusion at a higher hemoglobin level may be warranted.⁶⁸ The decision regarding intraoperative and postoperative transfusion should be based upon hemodynamic parameters (hypotension, tachycardia), and usually occurs at a hemoglobin concentration of 7 to 8 g/dL in patients without cardiac or central nervous system pathology.⁶⁸ A preoperative and intraoperative platelet count of 100,000/ μ L is necessary for hemostasis in neurosurgery, although much lower platelet counts are tolerated in general surgical patients (50,000/ μ L) and stable nonsurgical patients (10,000/ μ L).⁶⁹ Similarly, a prothrombin time (PT) of less than 16 seconds, an international normalized ratio (INR) of less than 1.2, and a partial thromboplastin time (PTT) of less than 39 seconds (depending on the norms at an individual institution) are necessary for intraoperative hemostasis, although values moderately outside of these limits do not produce bleeding difficulties in nonsurgical patients. The administration of fresh frozen plasma (FFP) has few guidelines but is generally recommended for patients with warfarin-related intracranial hemorrhage and for those undergoing massive transfusion.⁷⁰ Recent articles indicate that an INR of 1.5 (or possibly higher) does not produce increased bleeding in neurosurgical procedures, and that the administration of FFP produces fluid overload and an unnecessary delay in surgical intervention.⁷¹

A massive transfusion protocol has been established at the University of Pittsburgh for patients with major blood loss resulting from trauma or surgery (in whom the use of 10 units of packed red blood cells [PRBCs] is expected) in response to literature suggesting improved survival in patients transfused with high FFP- and platelet-to-red blood cell ratios.^{72–74} A pediatric massive transfusion protocol has been proposed, based on the same principles; triggers of persistent hemodynamic instability or ongoing bleeding after the infusion of 40 mL/kg of crystalloid are used to initiate the transfusion of PRBCs (30 mL/kg). The addition of FFP (20 mL/kg) is made after the loss of one blood volume, and the addition of platelets (20 mL/kg) and cryoprecipitate (4 mL/kg) after the loss of two blood volumes.⁷⁵ The off-label use of recombinant factor VII (Novoseven; Novo Nordisk, Plainsboro, NJ) can be considered in cases of continued blood loss.⁷⁵

4.2 Postoperative Management

4.2.1 Fluid and Electrolyte Management

Nearly all pediatric surgical patients (not only neurosurgical) are now placed on isotonic fluids (either NS or LR) in the

postoperative period.⁷⁶ It is clear that hypotonic maintenance IV fluids cause hyponatremia in children, with the potential for the development of hyponatremic encephalopathy, cerebral edema, and death in children who have severe infections or are in the postoperative state.⁷⁷ A trial in 258 postoperative patients revealed that hypotonic IV fluids (0.45% NS in this study) significantly increased the risk for hyponatremia compared with isotonic IV fluids (0.9% NS).⁷⁸ The development of hyponatremia is felt to be a function of the tonicity of the maintenance fluids, rather than of the volume of fluid administered.⁷⁹ Antidiuretic hormone (ADH) levels are normally elevated in the 24 hours following surgery, and fluid restriction delays the normalization of ADH levels.⁸⁰ Sodium losses from an EVD can warrant replacement if hyponatremia develops. Postoperatively, it is common for neurosurgical patients to be placed on NS.

Sodium levels are strictly maintained at the upper limit of normal or higher (140 to 150 mEq/L is a fairly standard range) in the majority of pediatric neurosurgical patients. The blood–brain barrier is often disrupted at least locally in these patients, allowing the passive diffusion of water into the brain and a corresponding increase in cerebral edema and intracranial pressure. The blood–brain barrier comprises tight junctions between the endothelial cells lining the capillaries of the brain; the astrocytic foot processes surrounding the capillaries may play a minor role as well. The blood–brain barrier is disrupted by prematurity, infection, ischemia and stroke, neoplasia, hypertension exceeding the limits of autoregulation, and trauma (including surgery).⁸¹ It can be intentionally disrupted with the use of hyperosmolar solutions, such as mannitol, to improve the delivery of chemotherapeutics. Increasing the sodium level in the bloodstream decreases the amount of free water in the brain, both intracellularly and extracellularly. The IV use of hypertonic saline or mannitol exerts an osmotic pressure gradient across the blood–brain barrier, allowing water to diffuse down the osmotic pressure gradient into the bloodstream. When the blood–brain barrier is disrupted, these molecules freely enter the brain through the widened tight junctions, leading to edema, excitotoxicity secondary to the accumulation of excitatory amino acids, and the loss of cerebral autoregulation. Steroids and hypothermia are thought to reduce the permeability of the blood–brain barrier.

Hypertonic saline at various concentrations, with 3% NS the most common (a bolus dose of 3 to 10 mL/kg or a continuous infusion beginning at 1 mL/kg/h and increased to effect), is used as a treatment for intracranial pressure (ICP) above 20 mm Hg in pediatric traumatic brain injury, titrated to an ICP below 20 mm Hg and a serum osmolality below 360 mOsm/L.⁸² Mannitol is also frequently used, although clinical studies demonstrating its efficacy are lacking.⁸² Doses of 1 g/kg reduce ICP through a reduction in blood viscosity in the short term (less than 75 minutes) and through an osmotic effect lasting up to 6 hours. This effect requires an intact blood–brain barrier; mannitol may diffuse into injured areas of the brain, pulling free water into the parenchyma.^{83,84} 3% NS functions via similar mechanisms, although much higher serum osmolality is tolerated by patients given 3% NS than by those given mannitol.⁸⁵ 3% NS is also useful in treating cerebral salt wasting.

4.2.2 Perioperative Medications

Antiepileptic drugs (AEDs) are often administered prophylactically in the perioperative period. The risk for postoperative epilepsy ranges from 12 to 17%.^{86,87} The administration of phenytoin in the perioperative period was shown to reduce the chances of postoperative epilepsy from 17 to 8% in a double-blinded trial of 203 patients undergoing craniotomy.⁸⁸ The chances of perioperative seizure can be increased (sevoflurane, enflurane) or decreased (thiopental, halothane) by the use of certain anesthetics.⁸⁹ A seizure can be induced in a patient with epilepsy by using anesthetics that are not proconvulsant in the normal brain (e.g., ketamine, isoflurane).⁸⁹ The same anesthetic drug can be proconvulsant or anticonvulsant, depending on the clinical setting and dose.⁹⁰ Risk factors for perioperative seizures include a supratentorial tumor, age younger than 2 years, and hyponatremia due to inappropriate secretion of antidiuretic hormone (SIADH) or cerebral salt wasting.⁹¹ Nonaccidental trauma, prehospital hypoxia, a Glasgow Coma Scale score of less than 8, and subdural hematoma have also been identified as risk factors for seizure in trauma patients.^{92,93}

AEDs decrease the early (<7 days) but not the late (>7 days) risk for seizure after head injury in adults.^{82,94,95} Studies have principally been performed with phenytoin, although carbamazepine and phenobarbital have also been shown to provide a reduction in early posttraumatic seizures.⁹⁵ The combination of phenytoin and phenobarbital appears to be the most effective in reducing provoked seizures; the majority of drugs developed after 1980 have not been tested.⁹⁶ Levetiracetam and phenytoin are both associated with a low risk for early postoperative seizures, and levetiracetam is associated with fewer early adverse reactions.⁹⁷ Some small studies of levetiracetam suggest equivalent seizure control and improved neurologic outcomes, but the numbers do not reach statistical significance, and this fact combined with the 20-fold higher cost of levetiracetam suggest that these data be interpreted with caution.^{98–100} Because of the higher rate of side effects with phenytoin, a common practice is to begin a patient on phenytoin perioperatively and switch to levetiracetam if any side effects occur. This transition has been shown to be safe in a small pilot study.¹⁰¹ Several small studies not reaching statistical significance failed to show a reduction in early posttraumatic seizures for phenytoin in children.¹⁰² No drug has been shown to reduce the incidence of late seizures following trauma or craniotomy. The effect on children is extrapolated to be the same as for adults, but confirming data do not exist.

The use of AEDs in children following head trauma and craniotomy for other reasons is controversial, and largely a matter of surgeon preference. A common management choice is to load a patient who has a tumor or vascular malformation with an AED at the start of surgery and continue the AED for some period of time thereafter. Although the literature does not support a role for AEDs in preventing late-onset epilepsy, it is certainly not ideal for the recovering brain, unfused craniotomy bone, and healing skin to be subjected to the trauma and hypertension associated with a generalized tonic-clonic seizure. Many pediatric neurosurgeons advocate 6 to 12 weeks of AED therapy after a craniotomy for this reason and taper the drug after that time point, with or without an electroencephalogram (EEG) before or after completion of the taper.

The routine use of perioperative dexamethasone to limit peritumoral cerebral edema was initiated in the 1960s.¹⁰³ The use of dexamethasone has expanded over the years, and it is now used by some surgeons for patients undergoing surgery for aneurysms or arteriovenous malformations, surgery for Chiari malformations, craniofacial surgery, or resection of epileptic foci, in addition to those with brain tumors. Dexamethasone, although accompanied by a host of side effects, including mood changes, increased oral intake, and acne, in addition to the classic cushingoid appearance (buffalo hump, moon facies, abdominal striae), produces an improvement in the neurologic examination findings in some patients, a reduction in nausea and vomiting, improved pain control, and a shortened hospital stay.^{104–106} Dexamethasone dosing if continued for 5 days must not be abruptly discontinued, to prevent acute adrenal insufficiency; rather, it must be tapered off over a minimum of 5 days, with the rate of recovery dependent upon the length of steroid administration.¹⁰⁷ Dexamethasone is a strong glucocorticoid agonist with little to no mineralocorticoid effect, whereas hydrocortisone is a stronger mineralocorticoid agonist than glucocorticoid agonist. Hydrocortisone is thus administered preferentially to patients who have primary or secondary adrenal insufficiency; a classic example is the patient with a craniopharyngioma. Stress dosing should be undertaken for surgery, illness, and fever in patients with panhypopituitarism or adrenal insufficiency.¹⁰⁸ Stress dosing is roughly three times the maintenance dose. The necessity of stress dosing has been questioned in many patients on long-term glucocorticoids, but not for neurosurgical patients; a patient receiving high-dose dexamethasone for cerebral edema does not require the additional administration of hydrocortisone.¹⁰⁸

A course of dexamethasone is highly effective in treating chemical, or aseptic, meningitis following a craniotomy. The secondary hydrocephalus often resolves after the first few days of a several-week tapering course of dexamethasone. These patients typically present with a fever and meningismus but are alert and interactive, whereas patients with bacterial meningitis are usually somnolent. Once infection has been ruled out with a lumbar puncture demonstrating the absence of bacteria and a lymphocytic predominance, a weight-dependent bolus of dexamethasone followed by regular dosing of a slowly tapering course over several weeks produces resolution of symptoms.

Blood pressure management is important, and often critical, in postoperative neurosurgical patients. Patients who have undergone craniotomies for tumor or epilepsy focus resection are predisposed to hemorrhage if allowed to become hypertensive. An upper limit is usually set for the systolic blood pressure (SBP), as intermittent spikes in blood pressure can be reasoned to override tenuous clot formation in, or coagulation of, a blood vessel, eliciting a significant intracranial hemorrhage; upper and lower limits for mean arterial pressures (MAPs) are also typically specified to ensure adequate perfusion of the brain while limiting venous ooze into the resection cavity. Blood pressure and heart rate norms vary with patient age and size, and intra- and postoperative targets should be adjusted accordingly. A general rule for adult patients is to keep the SBP under 140 to 160 mm Hg; in children, the baseline preoperative blood pressure is a good approximation of the goal postoperative blood pressure. β -Blockers (propranolol, metoprolol) reduce cardiac output by reducing contractility and the heart

rate. α -Blockers (prazosin, doxazosin) reduce afterload. Mixed α -/ β -antagonists (labetalol, carvedilol) may also be used. Calcium channel blockers (nicardipine, nifedipine, verapamil, diltiazem) reduce systemic vascular resistance with minimal effect on contractility. Nimodipine, a calcium channel blocker commonly used for adult patients with aneurysms to reduce the complications of vasospasm, may be used in children to treat or prevent vasospasm. However, the dose and efficacy of this strategy in children have not been established, and children seem to have many fewer complications of vasospasm (behavioral change, stroke) than do adults following aneurysmal subarachnoid hemorrhage.^{109,110} Angiotensin-converting enzyme (ACE) inhibitors (captopril, lisinopril) produce vasodilation by reducing the body's production of angiotensin, but they have prolonged durations of action and effects on renal function that limit their usefulness. Vasodilators (hydralazine, minoxidil) are also used for hypertensive control. Nitroprusside causes vasodilation as a nitric oxide donor to the vasculature, reducing afterload, without an effect on contractility. Although its short half-life allows rapid dose titration, the production of cyanide during its metabolism yields significant toxic potential. Nitroprusside may increase ICP by increasing cerebral venous blood volume and should be administered only as a drug of last resort, together with thiosulfate. β -Blockers and calcium channel blockers, particularly labetalol and nicardipine, are the antihypertensives most commonly used in the PICU for neurosurgical patients.

Hypotension, relative or absolute, may be equally harmful. Patients who have undergone AVM resection may develop normal perfusion pressure breakthrough (cerebral edema or hemorrhage, thought to be from altered cerebral autoregulation secondary to the restoration of normal blood flow to the chronically ischemic tissue surrounding the AVM) if allowed to achieve normotension.¹¹¹ Such patients should routinely be maintained at least at the lower limit of cerebral perfusion to reduce the chances of this dangerous syndrome developing. Patients with moyamoya syndrome and resultant altered cerebral autoregulation may have strokes at higher than anticipated cerebral perfusion pressure.¹¹² Patients in spinal shock may require augmentation of their blood pressure, as volume resuscitation is contraindicated in these patients. Selected patients may require the use of pressors to increase the MAP. Epinephrine and dopamine are β -receptor agonists at low doses and α -receptor agonists at high doses. Epinephrine has a narrow therapeutic range and carries a significant risk for adverse reactions; it is used principally for cardiac arrest and anaphylaxis. Low-dose dopamine (0.5 to 5 $\mu\text{g}/\text{kg}/\text{min}$) increases renal and cerebral blood flow. Intermediate-dose dopamine (5 to 15 $\mu\text{g}/\text{kg}/\text{min}$) increases cardiac output. High-dose dopamine (> 15 $\mu\text{g}/\text{kg}/\text{min}$) produces progressive systemic and pulmonary vasoconstriction, increasing afterload and limiting cardiac output. Dobutamine is principally a β_1 -agonist (increased cardiac output), although it has mild β_2 effects (vasodilation). Norepinephrine is an α -receptor agonist that increases systemic vascular resistance through diffuse vasoconstriction, an effect that overshadows its minor effect on cardiac output. This is a second-line drug used principally in septic shock. Dopamine and dobutamine are the drugs of choice for increasing MAPs in the PICU.

Nausea and vomiting are common side effects of general anesthesia, and their incidence is increased in children.¹¹³ Nausea is partially controlled by the frequent use of intra- and postoperative dexamethasone and histamine₂-blockers (such as famotidine and ranitidine) in neurosurgical patients. Anesthesiologists routinely administer at least one antiemetic drug during surgery. The drug of choice for prophylaxis and treatment is a serotonin (5-HT₃) antagonist, such as ondansetron (Zofran; GlaxoSmithKline, Philadelphia, PA). Antiemetics like metoclopramide (Reglan), prochlorperazine (Compazine; GlaxoSmithKline), and promethazine (Phenergan; Baxter, Deerfield, IL) have potential neurologic and respiratory side effects and should be used as second-line agents and with caution.

Constipation is exceedingly common postoperatively in pediatric patients. This is problematic, as Valsalva maneuvers increase the risk for pseudomeningocele formation and CSF leak. Constipation causes unnecessary pain for the postoperative patient and can needlessly prolong a hospital stay. Patients should be routinely started on an osmotic laxative, such as polyethylene glycol (MiraLax; MSD Consumer Care, Summit, NJ), which is extremely well tolerated by patients, as soon as they begin an oral diet. An emollient stool softener, such as docusate (Colace; Purdue, Stamford, CT), or stimulants, such as senna (Senekot; Purdue) and bisacodyl (Dulcolax; Boehringer Ingelheim, Ridgefield, CT), are more objectionable to pediatric patients because of their taste but are adequate alternatives. Enemas and suppositories are less often necessary when these medications are begun early in a patient's hospital course.

4.2.3 Pain Management

Pain control in surgical patients is a critically important issue. The accurate assessment of pediatric pain is an essential part of postoperative management, as it allows the prevention of both over- and underadministration of pain medication. Many institutions have developed a pediatric pain management service to assist practitioners with this management. The most commonly used scales are CRIES for neonates, the Wong-Baker FACES scale for toddlers, FLACC (*face, legs, activity, cry, consolability*) for slightly older children, and VAS (visual analog scale) in children older than 7 years.¹¹⁴⁻¹¹⁹ The administration of local anesthetic, either a long-acting medication (such as bupivacaine) at the start of surgery or a shorter-acting medication (such as lidocaine) at the end of surgery, is effective in providing several hours of postoperative craniotomy pain control.¹²⁰ Oral sucrose may be helpful in minimizing distress for neonates past 34 weeks of gestation. The usual dose is 0.5 to 1.5 mL of 24% sucrose, given by syringe 2 minutes before the procedure. Breast milk and glucose are reported to be equally effective. Swaddling and nonnutritive sucking are first-line pain-relieving measures in neonates and infants. Acetaminophen and ibuprofen are typically administered in preference to oral opioids. Many patients require only acetaminophen or ibuprofen after a proximal ventriculoperitoneal shunt revision. Several studies have suggested that ibuprofen provides better pain relief than codeine or acetaminophen with codeine in children with long bone fractures.^{121,122} Topical skin anesthetics, such as EMLA and amethocaine gel, should be considered before painful procedures like IV placement, lumbar puncture, or suturing in infants

and children when possible, to minimize the pain and distress associated with the procedure.¹²³

Opioid administration is common, although the topic is controversial. Many neurosurgeons limit opioid administration in their postoperative patients because of a concern that somnolence or vomiting from postoperative cerebral edema or hemorrhage could be dismissed as a medication side effect. Opioids are to be administered in a response-dependent manner. Side effects like respiratory depression and somnolence occur after pain control has been achieved, so opioids should not be withheld for pain control because of a fear of these side effects. The most commonly used IV medication is morphine; hydromorphone (Dilaudid; Purdue) is occasionally used as a second-line drug in patients whose pain is refractory. The use of IV opioids should always be considered in neonates, in whom oral opiates are not recommended, although acetaminophen is highly effective in these patients. A morphine dose of 0.02 to 0.05 mg/kg IV every 4 to 8 hours may be used with caution in neonates, with close monitoring for respiratory depression, as pharmacokinetics in this age group are variable.¹²⁴ Morphine metabolism is decreased in infants younger than 6 months of age, and infants correspondingly require lower doses of morphine for pain control.¹²⁵ When older patients begin tolerating an oral diet, the IV opioid is typically transitioned to an oral opioid like oxycodone or hydrocodone. These drugs are favored over codeine because they provide more consistent analgesia. Oral morphine is three times less potent than IV morphine, and dosing must be adjusted accordingly.¹²⁶ Pediatric patients are likely to develop symptoms of opioid withdrawal after as little as 5 days of fentanyl infusion and may require transition to a tapering dose of methadone.¹²⁷

Patient-controlled analgesia (PCA), although infrequently used in young children, provides superior pain control in children older than 5 years of age.¹²⁸ PCA by proxy (parental administration of opioid) has been shown to have an increased incidence of respiratory depression secondary to opioid overdose, and it must be used with caution and extensive education of the proxy user.¹²⁹ Medications like low-dose ketamine (a dissociative anesthetic) can be added to the PCA for improved pain control and decreased opioid administration. Epidural PCA is used in patients undergoing spinal surgery, although rarely in patients undergoing craniotomy. A continuous epidural morphine infusion, with or without bupivacaine, has been demonstrated to be highly effective in patients undergoing lumbar dorsal rhizotomy.¹³⁰ Meta-analyses have demonstrated that continuous epidural analgesia is more effective in controlling postoperative pain than IV opioids (via either PCA or intermittent administration).^{131,132} Patients having spinal surgery, to include posterior fossa surgery, frequently experience spasm in the paraspinal musculature. This responds well to the administration of diazepam (Valium) or cyclobenzaprine (Flexeril). These drugs have a sedating effect and must be administered with caution.

The use of IV ketorolac (Toradol; Roche, Nutley, NJ) has been controversial in neurosurgery. Many neurosurgeons are reluctant to use it because of a concern about postoperative hemorrhage. Reports exist in the literature describing the development of spinal epidural hematomas in patients on ketorolac. One such case report describes an elderly patient who developed a spinal epidural hematoma after a lumbar puncture

while on enoxaparin, aspirin, and ketorolac.¹³³ No reports of intracranial hemorrhage in patients receiving ketorolac exist in the literature to date. A study of 89 adult patients undergoing lumbar microdiscectomy demonstrated improved pain control and no increased bleeding (from surgical wound or by coagulation parameters) with a single dose of ketorolac administered at the termination of surgery.¹³⁴ Multiple studies have confirmed the absence of an increased risk for postsurgical bleeding with the use of ketorolac in children, with the possible exception of those undergoing tonsillectomy.¹³⁵ Ketorolac is not recommended for use in children younger than 1 year of age, although it is routinely used at Children's Hospital of Pittsburgh in infants who have subgaleal drains in place. An increased risk for bleeding has been demonstrated in infants younger than 21 days of age.¹³⁶ Ketorolac is routinely used at Children's Hospital of Pittsburgh in the postoperative setting, particularly for pain control in patients undergoing Chiari decompressions or craniostomy repair, starting as soon as immediately postoperatively. Some surgeons opt to begin therapy with ketorolac a day or two following surgery, if clinically warranted.

An additional concern centers on conflicting reports in the literature suggesting that the use of nonsteroidal anti-inflammatory medications may inhibit spinal fusion. An increased rate of pseudarthrosis is well reported in adults.¹³⁷⁻¹³⁹ More recent literature has indicated that the short-term use of ketorolac (48 hours postoperatively) has no effect on spinal fusion.¹⁴⁰ A predisposition to pseudarthrosis or nonunion has not been demonstrated in children following instrumentation for scoliosis.¹⁴¹ Ketorolac produces superior pain control with fewer side effects than opioids, and although the risks must be weighed, its use is highly effective in many patients.

4.2.4 Restriction of Activity

Activity restrictions are imposed regularly for pediatric neurosurgical patients. Little evidence exists, however, to guide these decisions. Only the results of practice surveys completed by practicing pediatric neurosurgeons exist for most clinical questions. Return to school or day care is an important consideration. Children are kept out of crowded situations like school or day care because of concerns regarding possible injury to the incision, pain production, bleeding into a resection cavity, infection, and possibly the management of new neurologic deficits. Most children are able to return to school or day care within 2 weeks of a craniotomy. Pain and limited mobility may prevent patients undergoing spinal surgery from returning to school for 4 to 6 weeks. Older children may need to remain out of school for a longer period of time and undergo home tutoring so that they will be at the same level academically as their peers when they return to the classroom. Most school districts are mandated to provide a home tutor for any patient deemed by a physician to be unable to return to school for 4 weeks.

It is logical that Valsalva maneuvers should be limited following intradural spinal or posterior fossa surgery for a period of time following surgery, to minimize pseudomeningocele formation or CSF leak. This author has not observed pseudomeningocele formation more than 6 weeks postoperatively and uses this time period to instruct families to limit Valsalva maneuvers. Patients are restricted from lifting more than 5 pounds, straining, and physical activity beyond walking during this time. Patients

are placed on stool softeners to limit constipation. Following the 6 weeks, these restrictions are lifted completely for the majority of patients. Patients who have undergone Chiari decompression undergo a slower mobilization regimen, with running and swimming permitted after 6 weeks and noncontact competitive sports permitted after 3 to 6 months, depending upon the patient and the sport. Return to gym class depends upon the patient's neurologic deficits and typically occurs at least 4 to 6 weeks following return to school.

Return to sports is a particularly urgent issue for many families. Cranial concerns include the strength of the fusion between the craniotomy bone and the skull, the risk for hemorrhage associated with neovascularization and scar tissue, and risks for CSF dynamic alteration.¹⁴² While return to sports following concussion has been widely discussed and multiple sets of guidelines exist, return to sports following craniotomy has not been studied in a systematic way. Current guidelines for sports-related concussion advise against return to play in patients with neurologic symptoms, with or without provocative testing.¹⁴³ This guideline should certainly be observed in patients recovering from a craniotomy. Any patient with permanent central neurologic deficits should be prohibited from a return to contact sports.¹⁴² Most neurosurgeons insist that computed tomography of the head demonstrate fusion of the craniotomy bone before an athlete is permitted to return to play.¹⁴⁴ Patients undergoing posterior fossa surgery should be counseled about the potential decrease in ligamentous stability at the craniocervical junction as a result of the surgical approach.

Return to sports following spinal injury or surgery is problematic, as well. Several issues make the pediatric spine more vulnerable to injury than the adult spine. The pediatric head is larger relative to the body than is the adult head, allowing increased momentum with rapid movement. The pediatric paraspinal muscle mass is relatively less well developed, smaller, and more flexible than that of the adult, rendering it less able to withstand significant forces. The ligaments of the pediatric spine are more flexible than those of the adult, allowing more movement within the vertebral column and resultant spinal cord injury, without an identifiable ligamentous injury. This mobility, combined with the frequent finding of cervical spinal stenosis, is thought to be responsible for the "stinger" phenomenon seen commonly in high school football players. A stable spine by established criteria (normal strength, full range of motion without pain, and the absence of compressive forces) is a baseline requirement for return to play. Patients who have undergone spinal fusion are prohibited from collision sports on a permanent basis by the majority of spinal surgeons, from contact sports by some, and from noncontact sports (golf, swimming) for a variable period of months following surgery.¹⁴⁵ The decision regarding return to play must be made by the neurosurgeon and parents in conjunction, as only the family can determine their level of risk aversion.

Restriction of unoperated patients from activity is controversial. Because of case reports in the literature regarding subdural hematoma formation following participation in sports, including basketball, soccer, and football, in patients with arachnoid cysts, counseling of the parents regarding the risks associated with contact sports is held.¹⁴⁶⁻¹⁴⁸ Both arachnoid cysts and asymptomatic Chiari malformations are viewed as relative contraindications to participation in contact sports.¹⁴²

Many pediatric neurosurgeons restrict patients with ventriculoperitoneal shunts from participating in contact sports, although the established risk for complications (including shunt disconnection and subdural hematoma formation) is well under 1%.¹⁴⁹ With little information in the literature to inform decision making, counseling of the family regarding the potentially serious consequences must be undertaken in these cases.

4.3 Conclusion

A final topic, critical to the care of the pediatric neurosurgical patient, is the relationship between the neurosurgeon and the parents of the patient. The parents have been placed in the excruciating role of trusting a relative stranger to cut open their child's body, fix a problem, and return the child to them in the same or better condition. They must acknowledge their inability to protect their child from the hardships of life, and even from the pain of surgery. They feel helpless and desperate. The stress for some families is intolerable. Extensive discussion of the risks and benefits of surgery, as well as the likely outcome, lessens the burden somewhat. We in pediatric neurosurgery frequently see families at the most stressful moments of their lives, and we must deal with them with the utmost sensitivity.

Pearls

- Chlorhexidine gluconate produces the greatest reduction in CFUs on a surgeon's hands after a surgical scrub or on a patient's skin after a preoperative preparation; one study has linked chlorhexidine skin preparation to a decreased rate of SSIs.
- Hyponatremia must be avoided in all hospitalized children, not only those undergoing craniotomies. The administration of hypotonic IV fluids is associated with hemolysis, cerebral edema, and death in children.
- The development of hyper- or hypoglycemia is also problematic, and the serum glucose must be meticulously monitored when a patient's status is NPO and the patient is not receiving dextrose in his or her IV fluids.
- Massive transfusion protocols have been developed for patients in whom a large surgical or traumatic blood loss is expected, as survival appears to be improved in patients transfused with high FFP- and platelet-to-red blood cell ratios.
- The use of ketorolac for pain control, although the risks must be weighed, is associated with superior pain control and decreased side effects relative to the use of opioids.
- Although one goal of surgery is to return the patient to his or her prior level of function, the return to sports is a highly individualized decision that must be made in conjunction with the patient's family.

5 Pediatric Neurosurgery in Developing Countries

A. Leland Albright and Benjamin C. Warf

Many physicians who have worked in developing countries, even for a brief time, have been impressed by the great numbers of children who present with advanced stages of hydrocephalus (HC) and other diseases (► Fig. 5.1). The most commonly encountered condition is infant HC, which if untreated leads to death by the age of 2 years in 50% of cases and to significant disability in the majority of survivors; nonetheless, most children with HC in sub-Saharan Africa (SSA) go untreated. The reasons are multiple, but one reason is the lack of neurosurgeons in the region. There are around 100 neurosurgeons spread across SSA.¹ If all infants with hydrocephalus had access to care in the centers where these neurosurgeons practice, the average annual case load for a neurosurgeon would be at least 1,000 operations per year if infant HC were all he or she treated, not counting additional operations for shunt failure and infection—clearly an untenable situation. In addition, families typically have very limited means for travel, and in regions with poor infrastructure or security concerns, travel can be dangerous as well as difficult.

Before being brought to a medical center, many children are taken to a “practitioner of traditional medicine,” who may treat them with herbs or with focal cautery in the region of the abnormality (► Fig. 5.2). Families able to access a center with neurosurgical capabilities may be frustrated by their inability to pay for the cost of treatment, which typically includes purchasing a shunt. Because the cost of even a baseline shunt is prohibitive for many families, some surgeons insert either a length of Silastic tubing, tying off the distal end and making cuts just about the tie to create “slit valves,” or insert a valveless infant feeding tube. Such shunts are economical and considered by some to be effective, particularly in treating postinfectious HC.

A further obstacle to treatment in these children is a lack of general awareness in regard to the nature of hydrocephalus and the fact that it is a treatable condition. In areas where HC treatment has not been previously available, the public should be made aware of the condition of infant HC, what it looks like,

and where to get help. Depending upon the local culture, it may be appropriate to emphasize that this is a treatable medical condition, not the result of spiritual forces. Experience in Uganda demonstrated that this may be done effectively through newspaper and radio informational announcements, the result of which was a gradual decline in the age and disease severity of patients presenting for treatment over several years.

This speaks not only to the burden of disease, but also to the lack of access to diagnosis and treatment. In SSA, the annual number of new cases of infant HC can be minimally estimated to be more than 90,000, and potentially more than 300,000.² We recently reported that, after the use of a mortality-adjusted minimal estimate of annual cases of infant HC in SSA (82,000), the annual economic burden is at least 1 billion U.S. dollars, and possibly as much as to 56 billion U.S. dollars (depending upon the economic methods employed).² In the same study, we demonstrated that the most conservative estimate of the benefit-to-cost ratio for treating HC is 7:1, with an upper bound estimate of 50:1.

5.1 Congenital Lesions

5.1.1 Hydrocephalus

The most common cause of infant HC throughout SSA is unknown, and the causes may vary regionally or have differences in referral patterns. A previous report suggested congenital causes of HC to be most common.⁴ At CURE Children’s Hospital of Uganda (CCHU), we found ventriculitis to be the most common cause of infant HC, accounting for 60% of the cases, with three-quarters of the infections occurring within the first month of life as a component of neonatal sepsis.⁵ We have presented evidence suggesting that *Acinetobacter* and related species may be the dominant infectious agents.⁶ This is in

Fig. 5.1 A 7-month-old child who presented with untreated occipital encephalocele and thoracic myelomeningocele.

Fig. 5.2 Thoracolumbar scars resulting from the treatment of back pain secondary to a spinal-intraspinal tuberculoma by a practitioner of traditional medicine.

contradistinction to neonatal sepsis and meningitis in developed countries, where group B streptococci and *Escherichia coli* predominate. We have also demonstrated that in Uganda, infection peaks are tightly linked to rainfall patterns.⁷ Similarly, at Kijabe Hospital in Kenya, the most common etiology of HC was reported to be prior infection among all patients older than 3 months; however, for those younger than 3 months at treatment, myelomeningocele was the more common etiology.⁸ Thus, it is possible that many cases of infant HC in this region might ultimately be avoided. Public health strategies for the effective prevention and treatment of neonatal sepsis are sorely needed.

Clinical Presentation

Whether postinfectious or associated with spina bifida, HC is most common in infants, who may present with head circumferences ranging from normal to more than 60 cm, and it is accompanied by the same symptoms and signs that are seen in developed countries. Infants are often anemic and malnourished, and they have higher risks for infection and poor wound healing after shunting. Computed tomography (CT) and magnetic resonance (MR) imaging are available in few centers; ultrasonography is more widely available. Ultrasound images permit measurements of the lateral and third ventricles; the fourth ventricle is seen less commonly unless it is grossly abnormal.

The ethical issue of whether to treat severe infantile HC is a recurring one. Infants who are not treated develop progressive macrocephaly, sometimes to head circumferences of 80 cm, and many die of aspiration pneumonia or malnutrition within 2 years. However, some infants live for several years, and their caregiver burden is enormous. Insertion of a ventriculoperitoneal (VP) shunt or treatment with endoscopic third ventriculostomy and choroid plexus cauterization (ETV/CPC) may have no benefit on the neurologic condition of some infants with severe HC, but the prevention of severe macrocephaly has considerable benefit for the caregivers—not only because of the reduced weight of the infant head but also because of fewer pressure ulcers in the parietal regions.

Medical Treatment

At times, the treatment of severe HC is futile. If insertion of a VP shunt is thought to carry unacceptable morbidity because of malnutrition, poor home environment, or ventriculitis, and if cerebrospinal fluid (CSF) production cannot be diminished by CPC, medical treatment with acetazolamide may be considered. Doses of 50 mg/kg per day have been reported to significantly diminish CSF production for up to 1 month; the longer-term effects are unknown.⁸

Treatment with Shunts

In the best of circumstances, shunts are expected to fail at least once in the first few years after placement. In the North American Shunt Design Trial, 61% of patients were free of shunt failure at 1 year and 47% at 2 years, with a shunt infection rate of 8.1%.⁹ Even though some have reported higher shunt complication rates for SSA,¹⁰ others have reported outcomes comparable to those in North America. In a prospective study of 195

consecutive children at CCHU with 90.3% 1-year follow-up, 54.5% of patients survived to 1 year with no shunt complications (including infection, wound complication, and shunt malfunction), with all shunt malfunctions occurring within the first 3 months.¹¹ In that study, the shunt infection rate in the first year was 9.7%. A subsequent survival analysis of 900 first-time shunt placements at CCHU demonstrated the infection rates at 30 days, 90 days, 6 months, 1 year, and 2 years to be 5.7%, 9.5%, 11.7%, 13.3%, and 15.2%, respectively.¹⁶ It was notable that although the majority of known infections occurred in the first 6 months, late shunt infections continued to occur over the 7-year time span of the study at a rate of about 1% per year. A *retrospective* analysis of 574 patients at Kijabe Hospital in Kenya, with a mean follow-up of 8.9 months in 76% of patients, demonstrated that 65% had no shunt complications within the first 2 years, and shunt infection was diagnosed in 9.1%.⁶ However, *prospectively* collected data in Kijabe indicate a current infection rate of 15 to 20%. In both of these institutions, the shunt predominantly used was the inexpensive Chhabra shunt, for which no difference was found, in regard to rates of shunt failure or infection in the first year, when it was compared in a randomized prospective trial with a shunt commonly used in North America that costs 20 times more.¹¹ Thus, it is encouraging that even when a very inexpensive shunt system is used, the expected outcome for shunt treatment in SSA may not be substantially different from that in more developed countries. Higher shunt complication rates would be expected because of previously cited factors, such as malnutrition, thin skin, anemia, and concurrent illnesses.

Ventriculoscopic Treatment

Rationale for Its Use in a Developing Country

Despite the potential for reasonable shunt outcomes in SSA, the obstacles to treatment access discussed above eliminate the safety net for shunt maintenance that we rely on in more developed nations. Once the fontanels of a child with a shunt are closed, an emergency shunt malfunction in a rural, “up country” location may end in disaster. For this reason, at CCHU, we aggressively pursued ETV as the primary treatment.³ We noted a lower risk for infection for ETV (<1%) compared with our shunt infection risk of around 10%. Also, most ETV failures occur within the first 6 months of treatment, when the fontanel is open and treatment failure tends to be visually obvious and less precipitous—in contradistinction to shunt failures, which continue to occur over the lifetime of the patient and can lead to rapid clinical deterioration.

Combined Endoscopic Third Ventriculostomy and Choroid Plexus Cauterization

The initial experience with ETV was encouraging, but we found, as have others, that young age increases the risk for ETV failure.³ Acting on the hypothesis that this was the result of decreased CSF absorption among infants with congenital causes of HC (e.g., aqueduct stenosis, fourth ventricular outlet obstruction), we began including lateral ventricle CPC bilaterally along with ETV to treat the residual “communicating” HC¹² (► Fig. 5.3). We found that for infants younger than 1 year of

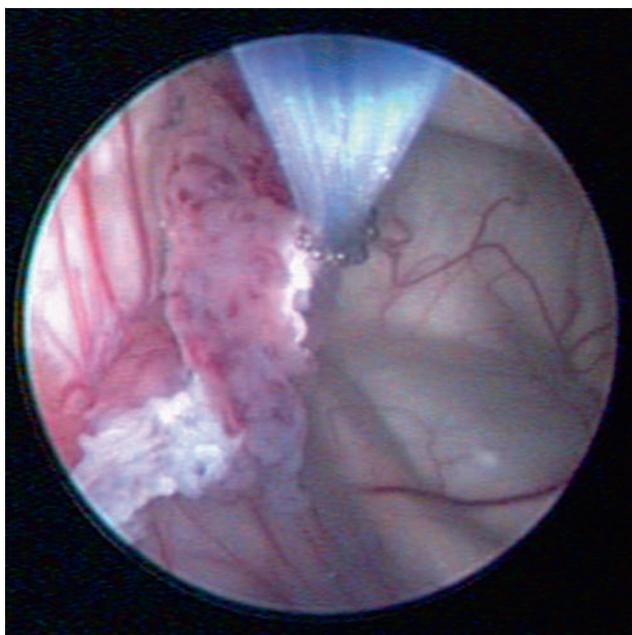

Fig. 5.3 Cauterization of choroid plexus in the lateral ventricle. Monopolar electrocauterization was performed with a Bugbee wire.

age, the addition of CPC significantly increased the overall success of ETV from 47% to 66% ($p < 0.0001$). The operative technique employed for the combined ETV/CPC procedure has been previously described in detail.^{12,13}

We subsequently demonstrated the efficacy of the combined ETV/CPC procedure for subsets of infants with HC of distinct etiologies, including postinfectious hydrocephalus (63.3%), myelomeningocele (76% success), encephalocele (79% success), Dandy-Walker complex (74%), and congenital aqueduct stenosis (81.9%).¹²⁻¹⁷ It is notable that the median age at the time of ETV/CPC in these reports was 2.0 months for infants with myelomeningocele, 3.0 months for infants with postinfectious HC, and 3.1 months for those with congenital aqueduct stenosis. Thus, these results are relevant for infants younger than 3 months of age. For infants with postinfectious HC, the outcome for ETV was more affected by the status of the aqueduct (open or closed) and the prepontine cistern (scarred or open) than by whether CPC was performed.^{12,14} Cisternal scarring is an especially good predictor of failure in these patients, more than doubling the risk for failure after control for other factors.¹⁸ Based upon our first attempt at ETV in 1400 patients, we were able to construct a success prediction score based upon patient age, the etiology of HC, and the extent of CPC.¹⁹ We are working to refine this by using the additional parameters of aqueduct and cistern status.

Mode of Hydrocephalus Treatment and Developmental Outcome

We were concerned that despite the potential benefits of being shunt-independent, there might be some developmental advantage to the treatment of HC by shunt placement, given the general impression that the ventricles tend to remain larger after ETV than with shunt placement. However, in a spina bifida

cohort, we were unable to detect any difference in early childhood development between children treated endoscopically and those treated with shunts.²⁰ Thus, there was no apparent developmental advantage for HC treatment with shunts that would dissuade us from continuing to pursue ETV/CPC as our primary treatment option.

Mode of Hydrocephalus Treatment and Survival

Our original impetus for pursuing endoscopic treatment was the assumption that shunt dependence would increase mortality in the long run, and thus its avoidance would actually save lives. However, we demonstrated no significant difference in 5-year survival between children treated by shunt placement and those successfully treated by ETV or ETV/CPC for myelomeningocele or postinfectious HC.²¹ The majority of deaths occurred from non-HC-related causes (mostly infectious diseases and malnutrition), and they were sufficiently common to obscure any small difference in survival that might have existed between the treatment groups. It was concerning that for these two groups of children, all of whom had some degree of disability, either from the myelomeningocele/Chiari type 2 malformation or the initial brain injury resulting from the neonatal infection causing postinfectious HC (which results in varying degrees of cerebral palsy), the 5-year survival was significantly less than that for their unaffected peers in Uganda. The 5-year survival of Ugandan infants in the general population is reported to be 84% (a child mortality rate of 16%). In the survival studies we conducted at CCHU, we found the 5-year survival for infants treated for postinfectious HC, myelomeningocele, and encephalocele to be 70.5%, 63%, and 61%, respectively.^{13,15,16} The increased mortality may have been related to several factors, including reduced access of disabled children to routine medical care, unrecognized symptoms of HC, or lack of care by their families. We found that the only factor favoring 5-year survival for the children with spina bifida was referral to a community-based rehabilitation program that included regular home visits. These children had significantly better 5-year survival (80%), which was equivalent to that of their unaffected peers.¹⁶ Patients who were not enrolled in one of these programs were three times more likely to die.

Effect of Prior Endoscopic Treatment on Subsequent Shunt Survival

We were concerned that for those patients in whom ETV was abandoned for shunt placement or for those undergoing shunt placement in the face of a successfully completed, but failed, ETV (\pm CPC), there might be an increased risk for shunt infection or obstruction as a result of the endoscopic procedure. However, in a retrospective study of 900 consecutive shunt placements at CCHU, we found no difference in risk for shunt infection or failure among patients who received a shunt primarily, at the time of an abandoned ETV (\pm CPC), or following a completed but failed ETV (\pm CPC).²²

Economic Impact of Primary Endoscopic Treatment

In the CCHU experience, in which 60% of patients have postinfectious HC, the ETV attempt has to be aborted in about 30% of

patients because of anatomical distortion (primarily from prior ventriculitis in those with postinfectious HC). Nonetheless, about half of all patients presenting for treatment are successfully treated with a single endoscopic operation and avoid shunt dependence. The average total financial cost of endoscopic treatment at CCHU in 2005 was \$670, and the cost of initial shunt placement was \$470 (when the inexpensive Chhabra shunts were used, each of which costs less than \$40).²² However, with a conservative estimate of two anticipated shunt revisions over time, and ignoring the additional cost for shunt infection, the total cost of initial placement and subsequent maintenance of shunt function was determined to be \$1,545 over time.²² Avoiding this cost in 50% of patients by attempting endoscopic treatment in all patients would create a potential savings of \$43,750 for every 100 patients presenting for treatment, an appreciable amount in resource-poor settings.

Training

Given the apparent advantages of attempting endoscopic treatment for HC as the primary method, we have advocated the training and equipping of neurosurgeons in developing countries in these techniques. The level of sophistication and skill required by the variable and sometimes difficult anatomy and the medical fragility of many of these infants have compelled us to focus our training efforts on neurosurgeons, although we have successfully trained nonneurosurgeons from regions with no neurosurgeons in certain very select cases. Through CURE Hydrocephalus, a division of the Christian nongovernment organization CURE International, fellows in neurosurgery are trained at CCHU, and after successful completion of their training, their home institutions are provided with the necessary equipment to develop their own programs. CURE Hydrocephalus also hires a local HC clinical coordinator for patient follow-up, given our reported observation that a home visit program may independently reduce mortality.¹⁶

Conclusion

It is unrealistic to expect long-term successful treatment of infant HC in developing countries with the model of visiting surgical teams that place shunts but are unable to provide follow-up or future access for the maintenance of shunt function. An argument can be made for placing the highest priority on training and equipping centers to provide competent longitudinal care. Furthermore, a strong case can be made for a policy of endoscopic treatment as the primary intervention, either by intention to treat in all patients or by refining the selection criteria according to established predictors of ETV success. The primary treatment of infant HC by ETV/CPC is more likely to be effective than ETV alone, and this treatment paradigm can dramatically reduce the incidence of shunt dependence—an especially important outcome in the context of countries with limited resources. This approach does not appear detrimental to developmental outcome, nor does it increase the subsequent risk for shunt malfunction or infection for those children in whom a shunt is ultimately required. The majority of ETV/CPC failures occur within the first few months of surgery, during a relatively safe period of infancy when failure is visibly obvious to the family and is not an acute emergency. Furthermore, a

paradigm of intention to treat by endoscopy may be more cost-effective in a given population. The increased mortality we have observed in disabled children can be mitigated with community-based rehabilitation or home visit programs, which should ideally be a component of any regional HC treatment center in the setting of a developing country.

5.1.2 Meningoceles and Myelomeningoceles

The incidence of meningocele (MC) and myelomeningocele (MMC) in developing countries appears to be significantly greater than that in developed countries, partly because of the lack of folic acid in diets, partly because of the ingestion of maize contaminated with the mycotoxin fumonisin (a folate antagonist),²³ partly because of the lack of prenatal screening and abortion, and partly because of the high birth rates in developing countries, such that the number of any congenital abnormalities would be increased. Approximately 300 infants come to Kijabe Hospital each year with untreated MMC. Few mothers of infants with MMC have heard about the benefit of folic acid in reducing the risk for MMC; they are given a year's supply of folic acid when their baby is discharged.

MC in developing countries seems to occur in the same ratio to MMC (~1:20) as in developed countries and to have the same presentation, imaging characteristics, treatment, and outcomes as in developed countries. However, MMC has a different spectrum; infants seem to have higher lesions, to have a greater likelihood of paraplegia or of an associated kyphus or split-cord malformation, and to be born with substantial HC.

Developing countries have few, and sometimes no, facilities to care for infants with MMC. Neurosurgeons and multidisciplinary care are rare, and if care is provided, it is often by a general surgeon who closes the back and/or inserts a VP shunt. Because children with MMC are a substantial drain on family resources, they are often not taken for treatment, and many die within a few months. Some centers insert a shunt but do not close the MMC, thinking that the baby's death would be the best outcome for both it and the family, and that in those infants who do survive, epithelium and then scar tissue will develop over the MMC.

MMC is rarely detected prenatally. Many deliveries occur at home or in rural hospitals, and transfer to facilities where care is available may be delayed because the family has insufficient funds to pay for the transportation, much less the medical care. Thus, although most children with MMC present within 2 months after birth, some do not present until 2 to 3 years later. When infants present within a few days after birth, some MMCs have ruptured. Even those that are intact may have become infected. In Kijabe, we analyze CSF from both the MMC sac and the ventricles on admission. CT or MR imaging is rarely available (or needed) before closure of the MMC, but lateral spine X-rays are helpful in evaluating kyphotic deformities (► Fig. 5.4).

The ethical aspects of closing MMCs in developing countries are complex and beyond the scope of this chapter. In Kijabe, we offer operations to nearly all children with MMC, but there are a few for whom the prognosis is so dismal that palliative care seems appropriate—for example, infants with MMC, severe malnutrition, and gram-negative ventriculitis.

At operation, some surgeons close the MMCs as they are closed in the United States, in-folding the lateral edges of the

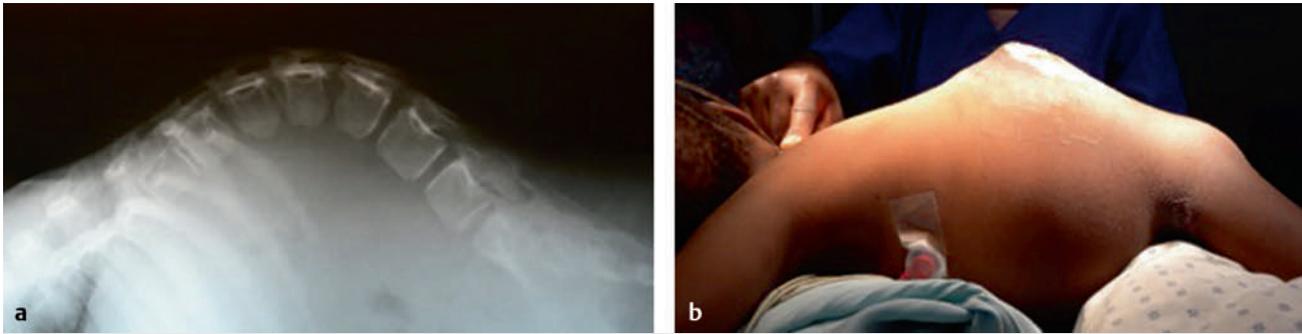

Fig. 5.4 Lateral spine radiographs of (a) an infant with a congenital kyphotic deformity associated with a myelomeningocele and (b) a 2-year-old child with a myelomeningocele-kyphotic deformity that was unrepaired at birth.

placode to the midline to “reconstitute” the cord, then covering it with semicircular leaflets of dura, then subcutaneous tissue and skin. However, a case can be made for doing distal cordectomies at the junction between the spinal cord and neural placode. Because placodes have minimal if any function, in our experience with many cases, motor function is rarely lost after distal cordectomies, and the risk for a subsequent tethered cord is probably decreased. For children who present with both MMC and clinically significant HC, a combined MMC closure and VP shunt or ETV/CPC can be considered *if* the child is afebrile, has a normal complete blood count, and has fewer than five white blood cells in CSF from the ventricles and from the MMC sac. In our Kenyan experience, approximately 15% of infants have an associated kyphus underlying the MMC. Because untreated kyphus frequently progresses in the following years, removal of the kyphotic vertebra and realignment of the spine by kyphectomy can be considered,²⁴ and this is performed routinely in Kijabe. Adjacent vertebral bodies can be held in alignment with large sutures (e.g., 0-Prolene) because infant vertebrae are too soft to hold screws, and then stabilized for 3 months postoperatively with a lumbar brace.

The frequency of complications after MMC closure is substantially higher than in the United States. Complications—including wound breakdown, infection, and CSF leak—occur in perhaps one-third of cases and reflect the underlying malnutrition, poor wound hygiene, and thin, taut tissues. Within the first week after operation, infants are begun on clean, intermittent bladder catheterization (CIC). Three months postoperatively, urodynamic studies and renal ultrasound scans are done to evaluate the need for continued CIC.

Follow-up care is usually infrequent and decreases as the children get older. Mortality data from Uganda with a 98% cohort follow-up indicate a 63% 5-year survival, with a threefold difference in survival between those who are in community follow-up programs and those who are not. Survival also depends on factors such as regularity of clean intermittent catheterization, development of decubiti, and availability of medical resources to evaluate and treat complications.

5.1.3 Lipomyelomeningoceles

Children with lipomyelomeningocele (LMMC) present from infancy throughout childhood, sometimes because of the obvious subcutaneous lumbar mass and sometimes because of pain,

bladder dysfunction, or leg weakness associated with the mass and tethered cord. Preoperative MR images are usually not available. Operations for children with LMMC should be done only by neurosurgeons experienced with these lesions; they are far more complex than those for MMC, and the frequency of complications is far higher. It is not uncommon to see a child in whom the superficial component of an LMMC had been excised by a general or pediatric surgeon who did not realize the underlying intraspinal component and tethered spinal cord. For neurosurgeons experienced in the care of children with LMMC, the surgical indications are the same as they are in developed countries. If an experienced neurosurgeon is not available, a case can be made to wait until neurologic signs or symptoms develop, a treatment paradigm supported by those who advocate that practice routinely.

Intraoperatively, the periphery of the fatty subcutaneous mass is exposed, then normal spinal cord cephalad to the LMMC is exposed through a laminectomy. Under magnification, the LMMC is dissected off the spinal cord; lasers are not available, but a needle tip cautery set at low voltage works acceptably. In general, the older the child, the more difficult the operation. The goal of operation is to untether the spinal cord, not to completely resect the mass and all intradural fat. The dura should be closed meticulously and the closure supplemented with overlying muscle and fascia if possible to decrease the risk for postoperative CSF leaks. In the Kenya experience, postoperative CSF leaks develop in perhaps half of the children, and closure of the leaks may require multiple procedures, occasionally even the insertion of a VP shunt. Morbidity of the operations depends on the anatomy of the lesion and the expertise of the neurosurgeon. The likelihood of recurrent LMMC tethering in developing countries is unknown, but it is probably similar to that in developed countries if children undergo similar operations.

5.1.4 Split-Cord Malformations

Split-cord malformation (SCM) appears to be more common in developing countries. In the Kenya series of patients with MMC operated on in infancy, approximately 15% have an associated SCM. An infant born with an MMC and asymmetric neurologic function in the lower extremities is more likely to have an SCM than a hemimyelomeningocele. The classic SCM indicators of lumbar hypertrichosis and scoliosis are uncommon in infants but

are often present in older children. Many SCMs are found only at the time of operation because many children undergo surgery on the basis of clinical signs and symptoms, without antecedent CT and MR imaging. The SCM may be associated with lipomeningoceles, neurenteric cysts, or other congenital anomalies.

The intraoperative treatment of SCM is similar to that in developed countries. In the series of 300 cases of SCM reported by Mahapatra, 20% of the patients with a neural tube defect had an SCM.²⁵ In his patients with SCM, skin stigmata were present in 65%, scoliosis in 50%, and foot deformities in 48%; motor and sensory deficits were present in 80% and 70%, respectively; postoperatively, 50% improved, 44% stabilized, and 6% worsened. Prophylactic operations are probably advisable for asymptomatic patients if experienced neurosurgeons are available because of the risk for insidiously worsening neurologic function and the difficulty of good follow-up over the years.

5.1.5 Chiari Malformations

Chiari type 1 malformations are rarely diagnosed in developing countries, primarily because MR imaging is rarely available to evaluate children who present with either posterior pain at the craniovertebral junction or scoliosis secondary to a syrinx. In infants with MMC, Chiari type 2 malformations may cause cervical hyperextension, swallowing difficulty, nasal regurgitation, aspiration, and stridor in the first 2 to 3 months after birth. In symptomatic infants, if the associated HC has not been treated, it should be. If infants are symptomatic and have a functioning shunt or ETV, Chiari decompressions can be considered if surgeons experienced with such operations are available. The operations can be done without preoperative imaging; the surgeon performs cervical laminectomies and dural opening from the foramen magnum caudally until the bottom of the herniated vermis is identified. A dural graft of pericranium or cervical fascia suffices if no cellulose grafts are available. Infants with Chiari type 2 malformations that are symptomatic at birth have such a poor prognosis that decompression is probably not advisable.

5.1.6 Encephaloceles

The ratio of occipital encephaloceles to frontal encephaloceles is approximately 50:50 in many developing countries, although in the Ugandan experience 48% were occipital, 30% sincipital, and 22% parietal.²⁶ Most children with occipital encephaloceles present within the first 6 months of life; the median age in Uganda was 1 month, with a mean of 17 months, and the mean age in Kenya was 4 months.²⁷ Encephaloceles are usually covered by skin, although occasionally by a membrane that may have ruptured. Surgical treatment involves resection of the abnormal skin and dural sac—leaving enough dura and skin to close the defect without undue tension—and involves the resection of herniated brain tissue. Although “expansion cranioplasties” have been reported as a means of preserving herniated brain, there is no evidence that neurologic function is improved if cerebral tissue in the encephalocele is preserved.²⁸ Alternatively, a frontal cranial expansion can be done to increase intracranial volume and allow the herniated contents to be positioned intracranially (A. K. Mahapatra, personal communication, 2012). Clinically significant HC developed in 33% of

children in the Ugandan series and in 36% in the Kenyan series.^{26,27} HC may be treated by ETV, ETV/CPC, or VP shunt. In the Ugandan series, 35 required treatment of HC—13 with ETV/CPC, 2 with ETV alone, and 13 with VP shunt. Successful treatment at 1 year was greater after ETV/CPC (79%) than after VP shunt (47%).

Children with sincipital encephaloceles seem to present at any age, from infancy onward. In an Indian series of 133 cases, 15 patients were 5 to 18 years old and 10 were older than 18 years.²⁹ In most large series, frontoethmoidal encephaloceles predominate. Cerebral tissue is present in sincipital encephaloceles, but the amount of tissue within them is generally less than in occipital encephaloceles, and the children are more likely to be mentally normal or nearly normal. HC has been reported in 17 to 36% of sincipital encephaloceles and agenesis of the corpus callosum in 12%.^{26,30} In our experience, most frontal encephaloceles are usually repaired best by combined facial and intracranial approaches, although in the Cambodian series, 21% of cases were treated by a transcranial approach, without a facial incision.³¹ Hypertelorism frequently accompanies frontal encephaloceles and may be treated by the classic Tessier procedure or by medial repositioning of the medial orbital walls.^{30,32}

5.1.7 Craniosynostosis

In the United States, sagittal and metopic synostoses predominate; in developing countries, coronal and syndromic synostoses are more common.³³ Cranial deformities associated with craniosynostosis (CS) in developing countries are often considered to be cosmetic problems not requiring medical intervention, and children are often brought for medical evaluation long after infancy (► Fig. 5.5). CS in developing countries is treated only in centers with neurosurgeons and is therefore uncommon. Even in centers where a neurosurgeon is present, operations are infrequent: Balasubramaniam and Rao reported only 70 cases in 10 years.³³ Orbitofrontal advancements in developing countries rely on stainless steel wires for bone fixation because absorbable or titanium plates and screws are rarely available.

5.2 Tumors

5.2.1 Scalp and Skull Masses

The most common location for a subcutaneous dermoid cyst in the United States is at the lateral aspect of the eyebrow. In Kenya, the most common location is at the anterior fontanel, where the cyst enlarges slowly but inexorably until removed, sometimes reaching a diameter of 8 to 10 cm in teenagers. Although dermoid cysts in infants erode the underlying bone, giant dermoid cysts seem to do so less often.

Eosinophilic granulomas have been seen less often in our experience than in the United States, but when they occur, they present in the same way—as tender, subcutaneous masses that develop after infancy, with irregular, moth-eaten, lytic skull defects visible on X-ray films. Although some eosinophilic granulomas regress over time when evaluated by repeated examinations and X-rays, such watchful waiting is less appropriate in developing countries because follow-up visits are more difficult for the families and therefore less likely to occur.

Fig. 5.5 Untreated Kleeblattschadel deformity in a 7-year-old child who presented for medical evaluation of an unrepaired abdominal omphalocele.

5.2.2 Supratentorial and Infratentorial Tumors

Children with brain tumors present late, and they are often blind because of chronic untreated HC and often cachectic because of repeated vomiting and poor nutritional intake. The tumors are more likely to be diagnosed by CT scans than by MR images, and they are usually large.

The surgical goal of treating children with supratentorial gliomas is similar to that in developed countries—total or extensive resections, which, because of the dearth of instruments like ultrasonic aspirators, are frequently done with suction, bipolar cautery, and pituitary forceps. The scarcity of postoperative radiotherapy and chemotherapy increases the importance of maximal resections. The management of craniopharyngiomas is particularly problematic. If tumors are predominantly monocystic, the intracystic injection of bleomycin (2 to 3 mg three times a week for 3 to 5 weeks) via a subcutaneous reservoir and intracyst catheter is appropriate.³⁴ When a craniopharyngioma is associated multiple large cysts above the inferior solid tumor component, the cysts can be effectively removed via a transcallosal approach to “buy time” for the child to reach an age when radiotherapy has fewer complications. It is appropriate to

attempt complete resection of a craniopharyngioma only in the rare circumstances in which the family has the means of providing lifelong multiple-hormone replacement and the neurosurgeon has considerable experience with such resections.

The same four infratentorial tumors—pilocytic astrocytomas, medulloblastomas, ependymomas, and brainstem gliomas—occur in developing countries as in developed ones, but their management differs considerably because of the infrequent availability of postoperative radiotherapy and chemotherapy. The only posterior fossa tumors treated similarly in developing countries are pilocytic astrocytomas, for which the operative goal is complete excision. Ependymomas—whose prognosis is so greatly improved by complete resections—are less likely to be completely resected if they invade the brainstem; if the resection results in the need for a gastrostomy or tracheostomy, those modalities are associated with enormous problems after the child is discharged. Medulloblastomas are often subtotaly resected if a frozen section confirms the diagnosis, and postoperative staging with CSF analysis and craniospinal imaging with MR is rarely available or done. If postoperative craniospinal irradiation is done, it is often administered empirically with standard doses of radiation, without postoperative imaging of the spinal axis. If a diffuse brainstem glioma is demonstrated on scans, children are treated palliatively with corticosteroids and analgesics; there is no indication for operation, and their prognosis is too poor to use the limited radiotherapy resources.

5.3 Trauma

Most pediatric head injuries are managed by nonneurosurgeons. Closed head injuries are managed with intravenous fluids and (inappropriate) dexamethasone, without intracranial pressure monitoring or scans. If no scanner is available, the surgeon can make a bur hole at the coronal suture in the midpupillary line, insert a needle into the lateral ventricle, and inject air for a ventriculogram. If the ventriculogram demonstrates a midline shift of 1 cm or more, bur holes in the temporal region are indicated to determine if a hematoma is present, a traditional technique we have used on several occasions. Alternatively, the traditional technique of making three bur holes, one in the temporal region, one in the posterior frontal region, and one in the parietal region, will detect many hematomas. Open head injuries are often treated by general surgeons by closure of the scalp, with or without irrigation and débridement. The morbidity and mortality of traumatic brain injuries are far higher in developing countries than in developed countries.

5.4 Infectious Disorders

5.4.1 Brain Abscesses

Brain abscesses are relatively common in developing countries. Contributing factors include a higher incidence of immunosuppression associated with AIDS and incompletely treated otitis media. Otitis media has been the most common source of brain abscesses in developing countries, followed by scalp and skull abscesses and by cyanotic heart disease.³⁵ Abscesses are solitary in about 80% of cases, but the prognosis of children with multiloculate abscesses appears to be similar to that of children with

a solitary abscess. Pus from brain abscesses was cultured in a series of 118 Indian patients, and microorganisms were identified in 81 to 75% by culture and in 6% by Gram stain; 64% of the organisms were aerobic and 31% anaerobic, and 5% were mycobacteria and 1% fungi.³⁶ The most common organisms were *Streptococcus viridans* (24%), *Staphylococcus aureus* (14%), *Bacteroides* (10.5%), and *Peptostreptococcus* (10.5%). The overall mortality was 14.4%, with more deaths in patients with gram-negative infections (30%) than in those with gram-positive infections (9.5%).

Neurosurgical treatment is limited to children with abscesses of appreciable size (≥ 3 cm) and in locations that can be aspirated via a bur hole. Excision of an abscess capsule is rarely indicated. Two effective techniques are to localize the abscess with ultrasound guidance and to aspirate as much pus as possible, then to treat with antibiotics. Repeated aspirations are sometimes needed. Alternatively, a bur hole can be made and a red rubber catheter inserted into the center of the abscess to aspirate pus (which should be taken immediately for culture), leaving the catheter in the cavity and inserting a sterile safety pin through the catheter at the level of the scalp to prevent its inward migration. The catheter is transected 1 cm distal to the safety pin and gauze applied over the open distal end of the catheter to collect purulent drainage. The catheter can be shortened by 5 to 10 mm per day until it is out. Postoperative antibiotics usually consist of third-generation cephalosporins and metronidazole, often supplemented with intravenous chloramphenicol, which is rarely used in developed countries but has broad coverage of gram-positive and gram-negative organisms and good CSF penetration.

5.4.2 Tuberculomas

Tuberculomas are covered comprehensively in Chapter 79.

5.5 Spasticity and Movement Disorders

Children in developing countries with focal spasticity of the upper extremities can be effectively treated by selective fasciculotomies. Puligopu and Purohit treated 20 patients, mean age 13 years, with selective motor fasciculotomies of the musculocutaneous nerves (13), median nerves (24), and ulnar nerves (3) and observed significant reduction in spasticity and improvement in hand function.³⁷ Lumbar dorsal rhizotomies are effective treatment of spastic diplegia and can be done in resource-poor environments. Lumbar dorsal rhizotomies can be done effectively without neurophysiologic monitoring, with proportions of the dorsal nerves (usually 50 to 75%) divided based on the severity of spasticity in the affected muscles.³⁸ Monitoring responses is inconsistent, and in the experience of both authors, outcomes are no different whether monitoring is or is not used.³⁹ For children with spastic quadriplegia who require tone reduction in the upper and lower extremities to facilitate care or to diminish the development of contractures, combined cervical and lumbar dorsal rhizotomies performed during the same anesthetic session can provide effective relief. Children with focal dystonia of an upper extremity can be treated by cervical dorsal ventral

rhizotomies, dividing about 85% of the ventral roots to the upper extremities.⁴⁰

In developing countries, intrathecal baclofen and deep brain stimulation are essentially unavailable. We know of no good neurosurgical treatment for children with generalized dystonia or choreoathetosis that has not responded to oral medications.

Pearls

- Socioeconomic factors beyond the control of the neurosurgeon—such as malnutrition, anemia, poor hygiene, and concurrent illnesses—play a major role in the condition at presentation and the outcomes of children with neurosurgical disorders in developing countries.
- HC secondary to neonatal ventriculitis is far more common in limited-resource countries than in developed countries. The prevention of severe macrocephaly (head circumference > 60 cm), whether by VP shunt or ETV/CPC, markedly eases caregiver burden.
- The efficacy of the combined ETV/CPC procedure for infants with postinfectious HC is approximately 65%; for MMC, 75%; for encephalocele, 80%; for Dandy-Walker complex, 75%; and for congenital aqueduct stenosis, 80%.
- The 5-year survival rates of infants treated for postinfectious HC, MMC, and encephalocele are approximately 70%, 63%, and 61%, respectively.
- Infants with MMC, minimal lower extremity function, and associated kyphus can be effectively treated by distal cordectomy and kyphectomy when the initial MMC closure is done; distal cordectomy seems to be associated with no significant increase in neurologic deficit and may be associated with a lower risk for subsequent tethered spinal cord.
- Children with LMMC have a substantially higher rate of postoperative complications—particularly CSF leaks—than those with MMC and should be operated on only by neurosurgeons experienced with these procedures.
- Children with focal spasticity, spastic diplegia, or spastic quadriplegia can be effectively treated by peripheral fasciculotomies or dorsal rhizotomies, without electrophysiologic monitoring.

6 Ethical Issues in Pediatric Neurosurgery

Patrick J. McDonald and Nalin Gupta

Although there is no one definition of the term *ethics*, in general it encompasses the various approaches to understanding and examining moral behavior.¹ The study of ethics can be broadly classified into two areas: normative ethics and nonnormative ethics. Normative ethics seeks to answer the question “What ought I to do?” for a given moral dilemma, whereas nonnormative ethics simply describes how people reason and act in moral situations, without commenting on the inherent “rightness” of their actions. From Aristotle to Aquinas to Kant to Rawls, philosophers have for millennia written about morality and what constitutes ethical behavior.

The application of ethical principles to health care decision making, however, is a relatively young field. Various descriptions as *bioethics*, *biomedical ethics*, and *medical humanities*, among others, as a branch of normative ethics it seeks to define, analyze, and guide decision making in medicine as it relates to the moral issues that confront both health care providers, patients, and their families or surrogates. The formal, if somewhat cumbersome, definition of bioethics is “...the systematic study of the moral dimensions—including moral visions, decisions, conduct, and policies—of the life sciences and health care, employing a variety of ethical methodologies in an interdisciplinary setting.”²

The last three decades have seen tremendous growth in the field of biomedical ethics. Virtually all medical schools and many residency programs incorporate ethics teaching and/or training into their curricula.^{3–6} While the issue of whether one can teach “virtuous behavior” to a physician (or any other individual, for that matter) remains contentious, there is little doubt that the proliferation of ethics teaching has resulted in a heightened awareness of ethical issues and dilemmas in medicine.

There is perhaps no other specialty in medicine that is confronted with ethical issues and dilemmas on a daily basis more than pediatric neurologic surgery. On an ongoing basis, pediatric neurosurgeons make medical decisions regarding problems ranging from severe congenital nervous system malformations, to premature newborns, to quality-of-life and end-of-life issues that have profound ethical, spiritual, and religious consequences.

The purpose of this chapter is to trace the history and development of modern biomedical ethics, review the basic principles of ethics and ethical frameworks, and provide an overview of some of the more common ethical issues faced by pediatric neurosurgeons. In addition, specific issues commonly encountered in practice are analyzed in an attempt to provide pediatric neurosurgeons with the tools necessary to assist them in reaching decisions when confronted with difficult ethical situations.

A common misconception regarding bioethics and those who provide an ethics consultation service is that there is one “right” answer for a given moral or ethical dilemma. Those who have sought the opinion of ethicists may often complain that in the end they are not given enough direction as to the correct course of action; in essence, they are not given an “answer.” Often, the correct course of action is profoundly influenced by the experience, cultural background, priorities, and subjective desires of the individuals involved, as well as their perceptions

of the importance of the issues at hand. Similarly, this chapter does not purport to have any one answer for all the ethical problems encountered in the practice of pediatric neurosurgery. We cannot be worse off, however, for having examined in a critical and thoughtful way, from our own personal standpoint, the difficult issues that confront our young patients and their families. In the end, this ongoing reflection may, and perhaps should, result in a continual re-evaluation of our own biases toward what “one ought to do.” A bioethical analysis resides in a middle ground between things that seem to be incontrovertibly factual and those that are entirely subjective.

6.1 History of Biomedical Ethics

The roots of bioethics date back to the fifth century BC, when Hippocrates, considered the greatest physician of his era, codified his understanding of how a physician should act into the Oath of Hippocrates. Medical students today still recite a modified version of the original oath upon graduation. The birth of modern-day bioethics occurred in the late 1940s, largely in response to the atrocities committed by Nazi physicians during the Second World War. The trial of Nazi doctors at Nuremberg, Germany, from 1946 to 1947 resulted in the formulation of the Nuremberg Code, which outlines a list of requirements for the ethical conduct of research on human subjects.⁷ The Nuremberg Code has been largely replaced by the World Medical Federation Declaration of Helsinki—Ethical Principles for Medical Research Involving Human Subjects, last revised in 2008.⁸

What is now recognized as the field of bioethics began to evolve in the 1960s in response to rapid changes in medical technology and therapies. Over the course of the last three or four decades, bioethics has staked a claim as a distinct discipline within the traditional health sciences. Many health care institutions now have clearly identified ethics departments, usually functioning as a consultative service to other clinical departments, in addition to existing hospital ethics committees and institutional review boards (IRBs) or research ethics boards (REBs). Clinical bioethicists come from varying backgrounds, including philosophy, medicine, nursing, and law. Although the field is relatively new, the questions it seeks to address are timeless: “They turn on the meaning of life and death, the bearing of pain and suffering, the right and power to control one’s life, and our common duties to each other.”²

6.2 Ethical Frameworks

In both the teaching of bioethics and the application of bioethics to clinical medicine, ethicists use a variety of ethical frameworks—specific lenses through which a particular ethical issue can be seen—to better outline the crux of the ethical matter at hand. Although not an exhaustive summary, the following paragraphs give a brief introduction to some of the more commonly used ethical frameworks. For those interested in further reading about the individual frameworks, more detailed information is available in the references cited.

6.2.1 Principlism

The term *principlism* refers to what are commonly known as the “four pillars” of modern bioethics as outlined by Beauchamp and Childress¹: autonomy, nonmaleficence, beneficence, and justice. These principles are the most commonly taught concepts in bioethics in medical schools today and are summarized below.

Respect for Autonomy

Autonomy (derived from the Greek words for “self-rule”), simply put, respects the ability of competent persons to make informed decisions regarding their medical care. In the last 30 years, the concept of autonomy has superseded the tradition of beneficent paternalism, in which patients essentially trusted that their physicians would make appropriate decisions, both medically and ethically, on their behalf. Autonomy is at the core of the concept of informed consent, in that a person cannot make a truly autonomous decision without fully understanding the risks, benefits, and alternatives to the proposed therapy. Pediatric neurosurgeons deal with the difficulties associated with the concept of autonomy in that many of our patients, by virtue of their age, disease, and developmental status or because of statutory restrictions, do not have the ability to make decisions on their own. As such, we must rely on substitute decision makers—in most cases, their parents. A common criticism of Western bioethics is the perceived overemphasis on the principle of autonomy.

Nonmaleficence

Primum non nocere (“first do no harm”), based on Hippocratic principles, effectively summarizes the principle of nonmaleficence. Because virtually every intervention in medicine, especially in pediatric neurosurgery, carries with it the potential to do harm, it may be better to express the principle of nonmaleficence in terms of exposure to undue risk of harm or deliberate intent to harm. The principle of nonmaleficence and the importance of intent are often cited when withholding versus withdrawing treatment and killing versus letting die are contrasted.

Beneficence

Beneficence refers to the act of doing or producing good or performing acts of kindness and charity.⁹ In the context of medical interventions, the intent or hoped-for outcome of an intervention must have a reasonable chance of producing some benefit to the patient or, conversely, of preventing or lessening the harm coming to the patient from his or her disease.

Justice

Perhaps the most controversial of the four principles, justice is variously described as what is fair or deserved, or what one is entitled to. “Distributive” justice “...refers to fair, equitable, and appropriate distribution determined by justified norms that structure the terms of social cooperation.”¹ The allocation of health care resources at all levels (micro, meso, and macro), rationing, and priority setting in health care institutions are all issues in which the principle of justice plays a key role.

Although beyond the scope of this chapter, the ongoing heated debate on health care reform in the United States centers on different interpretations of the definition of justice as it applies to the allocation of health care resources.

6.2.2 Utilitarianism and Consequentialism

Based on the theories of the 19th century philosophers Jeremy Bentham and John Stuart Mill, utilitarianism states that the moral worth of an action is determined by its consequences.¹⁰ Moral decisions should seek to maximize the good; that is, given choices, one should choose that action that results in the greatest good for the greatest number of people. This is known as the principle of utility.

Utilitarian arguments are often used when decisions are made regarding the allocation of scarce resources in health care, such as the funding of expensive new technologies and the distribution of donated organs for transplant. One of the major criticisms of utilitarianism is that in theory it allows the interests of the majority to override what may be legitimate claims or rights of the minority. A utilitarian might argue that in pediatric neurosurgery, a resource-intensive subspecialty, funds could be more effectively utilized by diverting them to better prenatal care. Utilitarianism is a form of consequentialism, an ethical theory holding that the morality of an act is determined entirely by the consequences of that act.

6.2.3 Duty-Based Frameworks and Kantianism

In direct contradiction to consequentialist or utilitarian theory is the duty-based or “deontological” theory of moral reasoning. The work of the 18th century Prussian philosopher Immanuel Kant, *Critique of Pure Reason*, is the basis of duty-based ethical frameworks, and this moral framework is more popularly known as Kantianism. Kant’s “categorical imperative” states that one “...should act only according to that maxim which you can at the same time will that it become a universal law.”¹¹ Thus, the moral worth of an action is based on whether it conforms to this rule of obligation. These obligations or imperatives can be derived from pure reason and are not dependent, according to Kant, on culture, tradition, or emotion. As an example, for Kant, truth telling is always morally obligatory, as one cannot construe a maxim in which lying would be considered universally acceptable. A major criticism of duty-based or Kantian moral theory is that it offers no solutions when duties or obligations conflict.

6.2.4 Communitarian Ethics

In contrast to the largely rights-based, individualistic theories summarized above, communitarianism seeks to make moral decisions based on communal values, goals, and traditions rather than individual rights and takes issue with more liberal theories that allow individual rights to trump the good of the community. The central question of communitarianism is “What is most conducive to a good society?” rather than “Is it harmful or does it violate autonomy?”¹²

6.2.5 Ethics of Care

Similar to communitarianism, an ethics-of-care framework does not seek to conform to set rules or moral theories. It highlights the role of relationships in making decisions and considers the values encountered in intimate personal relationships, such as love, compassion, fidelity, and sympathy, to be the most important factors in making decisions.^{13,14} Thus, in making a decision about aggressive care for a severely neurologically impaired child, factors such as the relationship of the child with other siblings and the impact of the child's illness on the entire family or community would be considered.

6.2.6 Casuistry

Casuistry is a branch of applied ethics based largely on the reasoning applied in common law. Rather than applying a particular ethical theory or framework to a given problem, casuistry looks at morality by examining cases. The correct course of action is determined by comparing the case at hand to "pure" or "paradigm" cases and determining if a similar course of action as taken in the paradigm case is warranted.^{15,16} For example, for end-of-life issues, the case of Karen Quinlan could serve as the paradigm case.¹⁷ Thus, morality stems from a social consensus as dictated by previous actions, rather than a set of rules or theories.

6.3 Ethical Issues

Some of the more commonly encountered ethical situations in pediatric neurosurgery are presented below, with illustrative cases and an accompanying discussion.

6.3.1 Quality of Life and Futility

The Cases of Baby K and Baby Jane Doe

Baby K was born with anencephaly. At the insistence of her mother, Baby K was intubated and ventilated after delivery. The recommendation for a "do not resuscitate" order was rejected by the mother, and eventually Baby K was weaned from the ventilator. After attempts to transfer the baby to another institution were unsuccessful, she was transferred to a nursing home. Episodes of respiratory distress and apnea resulted in multiple readmissions and an eventual tracheostomy. Despite a court-appointed guardian's recommendation for palliative measures only, the courts ultimately decided that the hospital was obligated to provide emergency treatment for respiratory distress. Baby K eventually died of a cardiac arrest at 2 years of age.

In 1983, Baby Jane Doe was born with an open neural tube defect. After being advised by physicians of a high risk for mental retardation and physical handicap, the parents of Jane Doe decided against surgical repair, despite the surgeon's recommendation that surgery be done, and asked that their child be provided nutrition and comfort measures only.

One of the more controversial topics in bioethics over the past 25 years has been medical futility and, stemming from this, quality of life—specifically, the following questions: Is there a threshold quality of life below which life cannot be considered

worth living, and if so, who makes this decision if the patient is unable to do so? The cases of Baby K and Baby Jane Doe illustrate these concepts.

Futility has been described as comprising four separate types¹⁸: physiologic futility (the intervention will not have its intended physiologic effect); imminent demise futility (the patient will die regardless of the intervention); lethal condition futility (the patient will die, no matter what the treatment); and qualitative futility (treatment is futile because quality of life is so poor). Others define futility as being either quantitative (in the last 100 cases, the proposed treatment has not been successful) or qualitative (the treatment prolongs life but simply preserves unconsciousness and dependence on intensive medical care).¹⁹ Despite these attempts at defining futility, the American Medical Association Council on Ethical and Judicial Affairs summed up the reality of the situation when it stated that "futility cannot be meaningfully defined" and that "denial of treatment should be justified by openly stated ethical principles and acceptable standards of care."²⁰ In the end, no one definition of futility may be adequate for every ethical situation.

In pediatric neurosurgery, decisions regarding futility can often place physicians in conflict with parents or guardians when parents either insist on treatment that a surgeon feels is futile or refuse treatment that the surgeon feels is indicated and in the child's best interests. Appeals to ethical principles do not necessarily resolve the conflict easily, as ethical principles can often conflict, especially with strongly held religious beliefs. A strict appeal to autonomy might dictate respecting the wishes of the parents even if a surgeon feels strongly that continued aggressive treatment or cessation of treatment may violate the principle of nonmaleficence.

When such conflict exists, it is important that neurosurgeons exercise care before deciding on a particular course. We suggest that the following steps be followed, as outlined by Brody and Halevy: (1) Parents or guardians should be involved in the decision-making process early on; (2) second opinions should be sought early and should be seen as a means of helping in the decision-making process; (3) when the conflict seems insurmountable, transfer of care to another physician should be considered; and (4) where available, institutional ethics consultation or review should be utilized.¹⁸ In rare circumstances, when conflicts cannot be resolved, legal remedies through the courts may need to be sought.

Quality of Life and Myelomeningocele—The Groningen Protocol

Euthanasia and physician-assisted suicide have been legal in the Netherlands since 1985. In 2005, pediatricians at the University Medical Center in Groningen, the Netherlands, outlined a protocol for euthanasia in newborns, commonly known as the Groningen Protocol.²¹ This protocol allows the use of lethal injection in newborns, with consideration of the following five criteria: (1) extremely poor quality of life (suffering) in terms of functional disability, pain, discomfort, poor prognosis, and hopelessness; (2) predicted lack of self-sufficiency; (3) predicted inability to communicate; (4) expected hospital dependency; (5) long life expectancy. In addition, parents are required to fully agree, and a team of physicians, at least one of whom is not involved in the care of the patient, must agree. All cases of

infant euthanasia are reviewed by a district attorney, and if the above criteria are not met, a physician may be prosecuted.

During a 7-year period from 1997 to 2004, 22 newborns were felt to meet the above criteria and hence received a lethal injection. Interestingly, all 22 of these infants were felt to have “severe spina bifida.” Not surprisingly, the publication of the Groningen Protocol resulted in considerable controversy and debate. In 2010, Barry published a rebuttal to the assumptions made in the Groningen Protocol, using both ethical and evidence-based principles to argue that “active non-voluntary euthanasia in neonates born with a myelomeningocele (MMC) must be condemned as unethical.”²² Barry argued that available evidence suggests that overall quality of life for persons with MMC is equal to that of age-matched controls.²³ The authors of the protocol argued that euthanasia is justified in infants for whom a life of intolerable suffering is expected. Barry rightly pointed out that there is no evidence that persons living with MMC live with a severe degree of pain and suffering.

The motivation of the authors of the Groningen Protocol was to save affected infants from a life of intolerable suffering and hopelessness—in essence arguing that death is a better outcome than life in these children. Although we agree that there may be circumstances, given extreme amounts of pain, suffering, and cognitive dysfunction, in which death may be a more favorable alternative to the continuation of pain and suffering, with no hope for an acceptable quality of life, it is rare that this is the case in children born with MMC.

The debate surrounding the Groningen Protocol speaks to ethical issues that may never be resolved: What is an acceptable quality of life? Is there a threshold below which life cannot be considered worth living, and if so, who decides?

Quality of Life for the Caregiver

Although one should always act in the best interest of the patient, there are occasions when a surgical intervention may benefit the caregiver more than the child. Neurosurgeons working in developing countries commonly encounter examples of severe hydrocephalus and extreme macrocephaly resulting in significant developmental delay. Surgical treatment in these cases may not alter the long-term neurologic outcome of the child but greatly eases the burdens on caregivers.

6.3.2 Informed Consent and Assent

John is a 16-year-old boy with Ewing sarcoma metastatic to the brain. In addition to the initial treatment of his paraspinal sarcoma, he has undergone a posterior fossa craniotomy to partially resect a dura-based cerebellopontine angle metastasis, followed by radiation and chemotherapy. He presents again with worsening headache and a recurrence of his cerebellopontine angle metastasis, as well as a second metastasis in the right temporal lobe. Repeated surgery followed by stereotactic radiosurgery for residual tumor is recommended as an option, but it is recognized by all that the prognosis is grim.²⁴ His parents wish to proceed with further treatment.

The day before surgery, John asks to speak with you. He states that he knows that it is unlikely he will survive and that he doesn't want any more surgery, but he doesn't want

to disappoint his parents. He says, “If it were up to me, I would refuse to have another operation.”

Parents and guardians have traditionally been considered substitute decision makers for their children when decisions related to health care are made. Many jurisdictions in North America have a statutory age of consent that may correspond to the age of majority in that jurisdiction. The evolution of the process of obtaining informed consent from a patient has paralleled the development of the ethical concept of autonomy; in essence, a competent patient must be fully informed of the risks, benefits, and alternatives to a proposed intervention in order to exercise his or her right to make autonomous decisions. Young patients may not, for the most part, have the capacity to fully understand the consequences of medical decision making and are not considered to be fully autonomous individuals. Given this, we ask their parents or guardians to act as surrogate decision makers.

The basis for surrogate decision making can vary, depending on the particular child and the age of the child. Substitute decision making or substituted judgment, the basis for most surrogate decisions in adults, seeks to determine what individuals would decide for themselves were they able to make the decision on their own. For young children, clearly it is difficult to infer what decision they would make had they the capacity to decide. As such, most surrogate decision making for children is done by using either the “best interests” standard or the “reasonable parent” standard.

The best interests standard allows guardians to balance the potential benefits of therapy with the risks of such treatment, taking into account the natural history of the disease process, treated or untreated. In contrast, the rational parent standard allows surrogates to make decisions based on their own values as parents, as long as they are reasonable.²⁵ The “reasonableness” of a decision can often be a legal determination.

When parents, as proxy decision makers for their children, act in a way that seems counter to the best interests of their children, physicians are not obligated to follow parental direction. Commonly encountered examples occur when parents decline life-saving treatment for their children on religious grounds. A substantial body of jurisprudence supports medical decision making based on the best interests of the child, rather than on the wishes of the parents: “Parents may be free to become martyrs themselves. But it does not follow that they are free, in identical circumstances, to make martyrs of their children.”²⁶ Clearly, surgeons should do all they can to make decisions in concert with families but are under no obligation, legally and morally, to provide or withhold treatment when they feel it to be in the best interests of young patients unable to provide consent themselves.

Although most children below the statutory age of consent do not have the legal authority to provide informed consent, it has become increasingly common to include children, especially adolescents, in the decision-making process. This has become popularly known as obtaining “assent” to treatment.²⁷ In a 1995 paper, the American Academy of Pediatrics Committee on Bioethics recommended that the concept of informed consent should be altered to one of “informed permission” from parents, and that when appropriate, assent to treatment should be obtained from the child.²⁸ Obtaining assent from a child includes informing the child, in an age-appropriate manner, of

the nature of the illness; explaining the likely course of action, including testing and therapy; and assessing the child's understanding of the situation and willingness to proceed (or refuse) the proposed treatment. In some legal jurisdictions, there is no legal age of consent for medical decision making, and it is left to the physician to decide if a child has the capacity to make medical decisions.

Clearly, the assent process is different for a 16-year-old than for a 9-year-old or a 4-year-old. There is evidence to suggest that the decision-making abilities of children as young as 14 are similar to those of adults in response to hypothetical medical dilemmas.²⁹ As the preceding case illustrates, adolescents may be able to make informed decisions regarding their health care before reaching the age of consent. This can be especially difficult for caregivers when those preferences are to refuse treatment.

6.3.3 End-of-Life Issues

A 13-year-old girl with a left frontal glioblastoma multiforme has undergone two separate resections as well as adjuvant radiation and chemotherapy. She presents with acute left-sided weakness, severe headache, and a computed tomographic (CT) scan showing progression of disease with hemorrhage into tumor that has invaded her contralateral hemisphere. The patient, her family, and caregivers decide on palliative measures only. The child's severe headache and nausea are treated with patient-controlled analgesia and antiemetics. After appropriate supports are put in place, the girl eventually dies comfortably at home, surrounded by family and friends.

The death of a patient is an event pediatric neurosurgeons face more frequently than many other physicians, whether it results from malignant neoplasms, trauma, or complex congenital neurologic disorders. Although there are no published data specific to pediatric neurosurgical patients, evidence in the pediatric critical care and pediatric oncology literature suggests that there are widespread deficiencies in the provision of pediatric palliative care.

Most consensus guidelines regarding end-of-life care see "no ethical distinction between withholding or withdrawal of life-sustaining treatment"³⁰ and suggest that physicians should "aggressively treat pain with analgesic drugs and, when needed, with heavy sedation, even if these treatments hasten death." The attitudes of pediatric neurosurgeons toward the withdrawal of life-sustaining care are not known, but in a survey of pediatric critical care physicians and nurses,^{31–34} none of the physicians surveyed felt that withholding or withdrawing life-sustaining care from dying children was unethical. Despite this, a survey of parents of children who had died of cancer showed that 89% of the children suffered "a lot" or "a great deal" in their last month of life, usually from pain, fatigue, or dyspnea.³⁵ This suggests that a greater awareness of the suffering and subsequent treatment of the suffering of dying children are needed. Pediatric neurosurgeons should play a leading role in ensuring that our patients with terminal illnesses die with the dignity and comfort they deserve.

6.3.4 Research and Children

A study on the transmission of hepatitis B took place at the Willowbrook School (an institution for developmentally challenged

children) in 1966. In the study, new residents at the school were intentionally infected with hepatitis in order to study transmission among residents. At the time of the study, hepatitis B was endemic in the institution, and most residents contracted the virus during their stay. It is unclear what parents were told about the process, and toward the end of the study, it was suggested that children whose parents agreed to allow them to participate were given preferential placement in the school.

The evolution of bioethics in the 20th century occurred largely in response to concerns related to human subjects research. The Nuremberg and Helsinki Codes came in response to Nazi atrocities in the Second World War,⁷ and many credit Henry Beecher's courageous paper on ethics and clinical research,³⁶ which detailed the Willowbrook study highlighted above, with starting the process of ethics review of human subjects research. Today, virtually every university and many hospitals have REBs or IRBs to review research protocols before they start. Many journals require REB or IRB approval as a prerequisite for publication.

Emanuel et al outlined seven requirements for the ethical conduct of human subjects research³⁷:

1. The research must be of value—that is, it has the potential to enhance health or knowledge.
2. It must be conducted such that the results are scientifically valid and methodologically rigorous.
3. Study populations and sites are chosen in a fair way—not based on vulnerability or privilege.
4. There must be a favorable risk–benefit ratio, with risks minimized and the potential for benefit to individuals and knowledge gained by society outweighing risks.
5. The research should be reviewed by unaffiliated individuals with the power to approve, amend, or terminate the research.
6. Participants must provide voluntary informed consent.
7. Subjects should have their privacy respected and have the ability to withdrawal from the trial.

Clinical research using children requires an even higher standard than research using competent adults, given that children are an especially vulnerable population. Although six of the seven requirements outlined by Emanuel et al can be applied to pediatric research, many children, by virtue of their age or capacity, are unable to provide informed consent. Issues of informed consent and pediatric patients have been referred to earlier, but there are distinct differences between consent for medical care, which is presumed to be of benefit to the patient, and consent to participate in clinical research, which may offer only the prospect of benefit and the potential for the assumption of risk without benefit.

Children are considered a potentially vulnerable population in research ethics. Kipnis outlines seven vulnerabilities in pediatric research subjects that should be considered by all investigators³⁸:

1. They commonly lack the capacity to make mature decisions.
2. They are subject to the authority of others.
3. They (and their parents) may be deferential in ways that can mask dissent.
4. Their rights and interests may be socially undervalued.

5. They may have acute medical conditions requiring immediate attention that make informed consent impractical.
6. They may have serious medical conditions that cannot be effectively treated.
7. They (and their parents) may lack access to social benefits such as health care.

Outside the context of clinical research, the concept of informed permission from surrogate decision makers has evolved for making decisions regarding medical treatment. Parental permission for pediatric research is increasingly being thought of as necessary but not sufficient for the ethical conduct of such research.³⁹ In addition to informed permission, the assent of the child involved in the research should be sought, when possible.³⁷ Obtaining assent recognizes and respects the developing autonomy of the child. Assent, however, should be seen as a continuum, based on the developmental level of the child, “ranging from mere affirmation in the youngest child, to the equivalent of the informed consent process in the mature adolescent.”⁴⁰

Current federal regulations in the United States allow IRBs to approve pediatric research if it conforms to one of three categories⁴¹:

1. Studies that offer participating children a prospect of direct benefit
2. Studies that do not offer a prospect of direct benefit but pose only minimal risk
3. Studies that do not offer a prospect of direct benefit and pose a minor increase over minimal risk

Minimal risk is defined as risk for harm or discomfort “ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.”⁴² Current debate centers on what constitutes a minimal risk or a minor increase over minimal risk, as these could be considered subjective. Much work continues and needs to be done regarding the ethics of clinical research in the pediatric population. In the end, a balance between the need for important clinical research in pediatric neurosurgery and the protection of potentially vulnerable research subjects must be found.

6.4 Surgical Innovation

Historically, novel surgical procedures have developed and been adopted into practice by a process of trial and error, with dissemination among peers through the publication of case reports and series and presentations at specialty meetings. Unlike novel pharmaceutical agents, which must undergo a rigorous process of regulatory review (which almost always involves randomized controlled trials), a new operation can be adopted without any regulatory oversight.

There is widespread acceptance that novel surgical therapies need to undergo a more rigorous validation process before they are adopted into practice by the broader surgical community.⁴³ The use of arthroscopic surgery for osteoarthritis of the knee is an example of a procedure in wide use that has been shown to be no better than medical management when studied in a randomized controlled fashion.⁴⁴

The ethical principles of beneficence and nonmaleficence underpin the argument for more rigorous evaluation of novel

surgical procedures. Even the simplest surgical procedure carries with it the potential risk for harm. If that procedure has not been shown to have a corresponding potential for benefit outweighing the risk for harm, than it is unethical for it to be widely adopted.

In response to these concerns, a group of methodologists and surgical clinicians known as the Balliol Collaboration developed a series of recommendations for the evaluation of surgical innovation, now known as the IDEAL recommendations.⁴⁵ These recommendations outline a five-step process consisting of the following:

1. An innovative idea (I), with a procedure done in selected patients and disseminated through case reports
2. Development (D), involving the planned use of a procedure in a small group of patients, by a selected number of surgeons to refine and modify techniques
3. Exploration (E), involving wider use of the procedure in more centers, with mentoring and the systematic capture of data, including adverse outcomes
4. Assessment (A), involving full evaluation of the novel procedure, ideally through a randomized controlled trial, and finally
5. Long-term study (L), allowing the capture of rare late complications and long-term outcomes. Of note, review by an IRB or an REB is required for steps 2, 3, and 4 and, depending on the nature of the innovation, may need to be sought for step 1.

Although started well before the IDEAL recommendations were published, the Management of Myelomeningocele Study (MOMS) is an excellent example of using rigorous methodology and practice to evaluate the efficacy of a procedure before its acceptance into practice.⁴⁶ Initial results of the fetal repair of MMC showed promise. However, because of concerns about premature adoption of the procedure as an acceptable standard of care, a decision was made by the pediatric neurosurgery community to halt expansion of the procedure to other North American centers and organize a randomized controlled trial. Pediatric neurosurgeons across North America agreed that no further fetal repair would be done outside the three study centers until its efficacy could be proven.

6.4.1 Fetal Surgery

The emergence of fetal intervention in the last two decades as a therapeutic option for lethal and nonlethal conditions diagnosed before delivery requires consideration of overlapping ethical issues. Most important of all is the balance between maternal risk and the benefit to her unborn fetus. Putting aside the psychological well-being of a mother who feels that her child's health has improved, the mother does not derive any direct physical benefit. The question remains whether the mother is able to provide a truly objective informed consent in this situation. This problem was approached in MOMS through multiple sessions in which providers allowed the mother to hear the risks and benefits repeatedly and from different perspectives. A final step was an evaluation of the mother's understanding by a social worker who was not a member of the actual treatment team. Inability to understand the issues presented was sufficient grounds to warrant exclusion from the study.

Dickens and Cook provide an excellent overview of some of the ethical and legal issues in fetal surgery.⁴⁷ These include controversial and as yet unresolved issues, such as whether a fetus has any inherent moral status, the potential conflict between maternal and fetal health, and whether the state should have any interest or say in fetal life.

6.5 Conclusion

Pediatric neurosurgeons encounter ethical and moral dilemmas frequently. An awareness of these issues and the ethical principles that surround them can help neurosurgeons to make decisions regarding the optimal treatment of our most vulnerable patients. This chapter has served as an introduction to the basic concepts of bioethics, with an emphasis on their application to pediatric neurosurgery.

Pearls

- A common misconception regarding bioethics is that there is one “right” answer for a given moral or ethical dilemma. The correct course of action is profoundly influenced by the experience and background of the individuals involved. A bioethical analysis resides in a middle ground between things that seem to be incontrovertibly factual and those that are entirely subjective.
- The “four pillars” of modern bioethics are autonomy, nonmaleficence, beneficence, and justice. Decisions should be guided by these basic goals.
- Children are considered a potentially vulnerable population in research ethics. There are specific vulnerabilities in pediatric research subjects that should be considered by all investigators.

7 Applications of Cellular Therapy in Pediatric Neurosurgery

Eric Thompson and Nate R. Selden

The development of cellular therapy, particularly stem cell (SC) therapy, for the treatment of central nervous system (CNS) disease has progressed rapidly in recent years. Scientists and translational clinicians have targeted SC therapy to broad categories of illness, from inherited metabolic diseases, such as neuronal ceroid lipofuscinosis (NCL), to neoplasms, such as brainstem gliomas. SCs have the potential to revolutionize therapy for previously untreatable CNS diseases. SC therapy, however, is challenged by scientific hurdles as well as by ethical controversy.

SCs have been defined as "...a population of cells capable of indefinite self-renewal that give rise to 'daughter' cells committed to specific differentiation lineages through asymmetrical cell division."¹ The term *stem cell* may refer to tissue derived from embryonic or adult sources, to cells with limited or unlimited potential to divide and replicate, and to cells that are already committed to neuronal, astrocytic, or oligodendrocytic lineages. *Asymmetric cell division* refers to the ability of a cell to produce a copy of itself plus a more differentiated cell, whereas *symmetric division* is the ability of a cell to produce two copies of itself.² Based on the local environment and the presence of various differentiation factors, SCs have the ability to differentiate into any cell type from any of the three germ cell layers. During differentiation, SCs pass through specific, stereotyped stages depending on lineage. For example, during differentiation into a neuron, an embryonic stem cell (ESC) must pass through the following stages: ESC, neuroepithelial cell, neural stem cell/progenitor, and neuron.^{3,4} Generally, as SC differentiates, its ability to self-renew and multiply diminishes.

The use of SCs in clinical translation is in its infancy. Very few human clinical trials are complete, with even fewer of these studying pediatric patients and diseases. This chapter first reviews the various types of SCs and their potential sources of origin for human therapy. We then contrast cellular therapy with strategies using other biological agents. We briefly outline various methods of delivering cellular therapy to the CNS and then review preclinical and, where available, clinical trials of cellular therapy for brain tumors, epilepsy, stroke, lysosomal storage disorders (LSDs), and spinal cord injury. Finally, we address limitations to the use of cellular therapy in children, including ethical considerations.

7.1 Sources of Stem Cells

7.1.1 Embryonic Stem Cells

ESCs are isolated from the inner cell layer of blastocysts that develop approximately 5 to 6 days following fertilization.^{1,5} ESCs are derived from the pre- or peri-implantation embryo, have the ability to undergo undifferentiated proliferation, and are capable of pluripotent differentiation into all three cell layers: ectoderm, mesoderm, and endoderm.⁵ Various ectodermal derivatives of ESCs include dopaminergic neurons⁶⁻⁸ and neural precursors,⁹ whereas mesodermal derivatives include blood vessels.¹⁰

Human ESCs may be retained in vitro for years and cultured with a high yield.^{11,12} They also have the potential for controlled differentiation and subsequent transplantation as neural stem cells (NSCs), astrocytes, or neurons. During normal development, ESCs within the neural plate differentiate based on their reciprocal interactions with surrounding cells and with gradients of morphogenic proteins, including Wnt, Shh, bone morphogenic protein (BMP), and fibroblast growth factors (FGFs).¹³ These biological variables can be used to direct the differentiation of ESC cultures in vitro for therapeutic purposes.

The use of ESCs for human therapy has been restricted because of their neoplastic potential. Because ESCs have the ability to robustly differentiate into all germ cell layers, teratoma formation has been reported in several animal models.¹⁴⁻¹⁶ In another animal model, undifferentiated neuroepithelial cell mitotic activity was found after ESC transplantation.¹⁷

At the time this chapter was written, only 152 ESC lines were eligible under U.S. federal regulations for use in National Institutes of Health (NIH)-funded research.¹⁸ For regulatory, practical, and ethical reasons, the supply of human ESCs is quite limited. Efforts to develop tools for cellular therapy with biological properties similar to those of ESCs have therefore garnered significant scientific attention in recent years.

Somatic Cell Nuclear Transfer

Somatic cell nuclear transfer (SCNT) involves replacement of the nuclear contents of an oocyte, or egg cell, with those of a somatic donor cell.⁵ The engineered cell is then artificially activated in a process analogous to fertilization by sperm and undergoes development. Using this technique, Rideout and colleagues replaced the *Rag2* gene in transplanted SCNT ESCs, producing allogeneic mature B and T cells in rodents with *Rag2* gene deletion, thus restoring their cellular and humoral immunity.¹⁹ In other studies, SCNT ESCs increased hemoglobin A protein levels and decreased polychromasia and anisocytosis in a mouse model of sickle cell anemia.²⁰ This approach may be used in the future to treat patients who have known gene deletions or mutations with SCNT ESCs containing normal copies of the specific missing or mutated gene. At the time of this writing, however, SCNT ESCs have not yet been established using a human ovum.

Transcription-Induced Pluripotency

Expression of genes normally active in ESCs can induce adult fibroblasts to enter a developmental state similar to that of ESCs.²¹ The four genes necessary to create these "induced pluripotent stem cells" (iPSCs) include *Oct3/4*, *Sox2*, *Klf4*, and *c-Myc*.²¹ The creation of iPSCs with fibroblasts from nonhuman primates,²² and soon thereafter from humans,²³ ignited intense public interest in these cells as an ethically benign alternative to ESCs for human clinical therapy.²⁴

Like ESCs, iPSCs demonstrate germline transmission of their genetic material. Unfortunately, as with other ESCs, a

substantial number of the offspring of transplanted animals develop teratomas, possibly because of the activation of *c-myc*.²³ This finding may limit the use of iPSCs in human therapy.

7.1.2 Adult Stem Cells

Adult stem cells (ASCs, sometimes also referred to as somatic stem cells) are multipotent progenitor cells, in distinction to pluripotent ESCs.⁵ ASCs are isolated from the brain, bone marrow, or other organ systems of humans or animals and can be cultured and expanded *in vitro*.^{25,26} Although they are referred to as “adult” SCs, the source of these cells in many cases is organ-specific fetal tissue. ASCs differentiate into cells of other tissue origin only via the process of “transdifferentiation.”^{27,28} ASCs grown in the presence of Lin28, Nanog, Sox2, and Oct4 exhibit many characteristics of ESCs, including pluripotency.²⁹ Such modified ASCs could be extracted from, modified, and reimplanted into the same patient, potentially avoiding immunologic complications and the ethical concerns arising from the use of ESCs in human therapy.

7.1.3 Primary Neural Cells

Primary neural cells (PNCs) are obtained from fetal cerebral tissue. PNCs cultured from human fetal mesencephalon were used in two clinical trials for the treatment of Parkinson disease (PD).^{30,31} Advantages of PNCs include a low risk for tumor formation and predictable phenotype.¹³ However, because they are already differentiated, PNCs largely lack the ability to expand in culture, significantly limiting their human therapeutic potential.

7.1.4 Neural Stem Cells

NSCs may be of embryonic or somatic origin.³² NSCs proliferate within the subventricular zone (SVZ) of mammals, follow a rostral migratory stream, and form new neurons within the olfactory bulb.^{33–35} NSCs are also responsible for the generation of new dentate gyrus granule cells in the hippocampus.^{36,37} Frequently, the terms *neural stem cell* (NSC) and *neural progenitor cell* (NPC) are used interchangeably. Unlike NSCs, however, NPCs are limited in their ability to self-replicate and typically do not form neurospheres.³⁸

Essentially, all NSCs derive from cells that produce glial fibrillary acidic protein (GFAP)³⁹ and give rise to neurons, glia, and oligodendrocytes.⁴⁰ A variety of trophic factors direct NSC differentiation into these specific cell lineages. Platelet-derived growth factor (PDGF),⁴¹ transforming growth factor- β_1 (TGF- β_1),⁴² neurogenin, mammalian AS-C homologue (MASH), and helix loop helix factor (HLH-f)⁴³ facilitate differentiation into neurons. BMP⁴² and leukemia inhibitory factor facilitate, while Noggin (a BMP inhibitor) interrupts, differentiation into astrocytes.^{43,44} Finally, insulin-like growth factor-1 (IGF-1) promotes oligodendrocytic differentiation.⁴² The expression of various transcription factors can similarly influence NSC differentiation.² Environmental factors also influence differentiation into CNS cell subtypes.^{45,46} One example is the differentiation of SCs into dopamine-producing neurons necessary for the treatment of PD.^{26,47}

7.1.5 Bone Marrow–Derived and Umbilical Cord Blood Stem Cells

Bone marrow–derived mesenchymal stem cells (BMSCs) are multipotent cells capable of re-creating lineages independent of the hematopoietic system. The key limitation to using BMSCs for treating CNS diseases is technical difficulty in inducing their transdifferentiation. However, BMSCs have the capability to differentiate into all three germ cell layers⁴⁸ and have been transdifferentiated into NSCs.^{49,50} BMSCs have been shown to cross the blood–brain barrier (BBB), thereby offering the potential for CNS vascular repair following stroke⁵¹ and remyelination following white matter injury.⁵² BMSCs may also have a neuroprotective effect, enhancing host neuronal survival after injury by releasing neurotrophic growth factors.⁵³

Umbilical cord blood (UCB) is also rich in mesenchymal SCs.⁵⁴ Engraftment rates may be higher for UCB than for BMSCs in treating Hurler syndrome,⁵⁵ although such differences are not consistent.⁵⁶ Advantages of UCB include low incidence of graft-versus-host disease, low risk for transmitting disease, rapid availability, and possibly a better graft rate than other hematopoietic SC sources.⁵⁷

Common sources of SCs are reviewed in ► Table 7.1.

7.2 Contrast to other Biological Agent Strategies

Cellular therapy follows a long line of rationally designed and targeted therapies for incurable and previously untreatable neurodegenerative diseases. This era of designed therapies began with the development of L-3,4-dihydroxyphenylalanine (L-DOPA) for the treatment of PD.⁵⁸ Although L-DOPA relieved some of the symptoms resulting from the degeneration of nigral dopaminergic neurons in patients with PD, it did not interfere with the inexorable underlying pathologic process. Subsequent developments in neurodegenerative disease therapy reflect both an attempt to more directly interrupt disease pathophysiology and growth in basic biological expertise in protein chemistry, genetics, and ultimately cellular therapy. Development of novel therapies for the incurable, inherited LSDs provides an example of this progress. The LSDs are characterized by the deficiency of an enzyme or enzymes that results in the accumulation of pathologic material in lysosomes, ultimately causing neuronal death and CNS dysfunction.

7.2.1 Enzyme Replacement Therapy

Intravenous (IV) enzyme replacement therapy (ERT) is the principal approach for treating many inherited enzyme deficiency diseases, including the LSDs⁵⁹ mucopolysaccharidosis (MPS) VI (Maroteaux-Lamy syndrome),⁶⁰ glycogen storage disease type 2 (Pompe disease),⁶¹ MPS I (Hurler syndrome),⁶² α -galactosidase A deficiency (Fabry disease), and glucocerebrosidase deficiency (Gaucher disease).⁶³

Hunter syndrome is caused by a deficiency of the lysosomal enzyme iduronate-2-sulfatase. IV infusion of idursulfase for Hunter syndrome has resulted in multiple somatic improvements, such as increased mobility, decreased hepatomegaly, and decreased respiratory infections.⁵⁹ IV delivery of idursulfase has not,

Table 7.1 Summary of cell types

Cell type	Donor source	Advantages	Disadvantages
Embryonic stem cells (ESCs)	Embryo	Undifferentiated proliferation Capable of differentiation into all three germ cell layers Long-term in vitro storage	Neoplastic potential Difficulty directing differentiation in vitro
Somatic cell nuclear transfer embryonic stem cells (SCNT ESCs)	Oocytes and somatic donor cells	Differentiation potential similar to that of ESCs	Efficacy not yet shown in humans
Induced pluripotent stem cells (iPSCs)	Adult fibroblasts plus specific genes	Avoids ethical issues of ESCs Differentiation potential similar to that of ESCs	Neoplastic potential
Adult stem cells (ASCs)	Developed organs (e.g., brain, bone marrow)	No immunocompatibility or ethical issues for autograft Expandable in vitro Safe	Restricted neural differentiation potential Questionable functional differentiation
Primary neural cells (PNCs)	Fetal cerebral tissue (mesencephalon)	Low neoplastic potential Predictable phenotype	Unable to expand in vitro Require stage-specific embryonic source Limited differentiation potential
Neural stem cells (NSCs)/ Neural progenitor cells (NPCs)	Embryo Subventricular zone of adults	Able to differentiate into neurons, glia, and oligodendrocytes Long-term vitro storage and expansion	Limited sources
Bone marrow–derived stem cells (BMSCs)	Bone marrow	Capable of differentiation into all three germ cell layers Crosses the blood–brain barrier Neuroprotective effects	Difficulty with transdifferentiation into NSCs

however, resulted in similar improvements in CNS function because of the relative failure of IV therapy to deliver replacement enzyme to the CNS.⁶⁴ In many disease states, ERT is completely ineffective because of BBB obstruction of CNS penetration.⁶³

7.2.2 Viral Vector Gene Therapy

The NCLs are examples of diseases untreatable with peripheral ERT. Late infantile NCL, an autosomal-recessive lysosomal storage disorder caused by mutation of the *CLN2* gene, results in profound deficiency of the lysosomal storage enzyme tripeptidyl peptidase 1 (TPP1), neuronal loss, progressive neurologic decline, and death.⁶⁵ Adeno-associated viruses (AAVs) can transfer human *CLN2* cDNA to genetically deficient cells in vitro and in rodent and primate animal models.⁶⁶ Gene transfer therapy increased levels of the deficient enzyme, TPP1, in the striatum, substantia nigra, frontal cerebral cortex, and thalamus of the injected hemisphere, and in the contralateral frontal cerebral cortex. Another group found similar results in an animal model of a related disorder, infantile NCL.⁶⁷

In a study of 10 children with late infantile NCL, AAV vector gene therapy may have slowed disease-related brain atrophy and neurologic deterioration compared with control subjects.⁶⁵ Given the low numbers of patients in this study, no difference in outcomes was statistically significant. Several adverse events were noted, including the death of one patient secondary to postoperative status epilepticus, as well as development of a humoral immunoresponse to the vector in four patients.

Gene replacement therapy is also being tested in animal models of other LSDs, including MPS VII (Sly syndrome) and MPS IIIB (Sanfilippo syndrome). In rodent models of MPS VII, direct intracerebral injection of the AAV2 vector, transplantation of retrovirus-transduced fibroblasts, and transplantation of adenovirus-transfected amniotic epithelial cells all reduced pathologic lysosomal storage.^{68–70} A similar viral gene therapy approach has been effective in a rodent model of MPS IIIB.⁷¹ This viral therapy strategy may be improved by using organ-specific NPCs.^{72,73}

Viral gene therapy for neurodegenerative disease faces a number of ongoing challenges. Individual viral vectors and genetic payloads must be designed for every genetic disease and disease variant. Each of these vectors must undergo extensive safety testing and regulatory approval.⁷⁴ The efficiency of transfection may be limited in many cases, and more efficient viruses may also pose a higher risk for associated pathologic inflammatory responses.⁷⁵ Finally, although they may spread by transfection, viruses have no inherent migratory potential. Thus, the delivery of the therapeutic agent to the entire expanse of the human nervous system in LSD is a daunting challenge and would likely require vascular delivery across the BBB.

7.3 Clinical Applications of Stem Cell Therapy

The inherent properties of SCs may prove advantageous in overcoming the daunting challenges of treating CNS neuro-

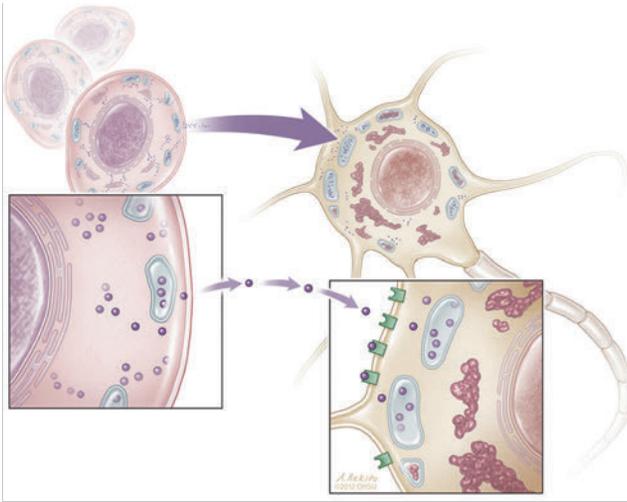

Fig. 7.1 Intercellular transfer of deficient enzymes from an intracerebrally transplanted neural stem cell to a neuron in a process known as metabolic cross-correction. Stem cells secrete active enzymes, which are then taken up by receptor-mediated endocytosis into enzyme-deficient neurons and transported to lysosomes, reducing precursor accumulation, normalizing lysosomal function, and protecting neurons from degeneration.¹³

degenerative disease. For example, implanted lineage-specific, or adult, SCs may survive indefinitely in the host environment, self-replicate or expand, and migrate significant distances within the CNS.^{76,77}

For LSDs and other enzyme deficiency diseases related to an isolated genetic defect, SCs may be used in a cross-correction strategy. In this circumstance, transplanted, genetically normal SCs produce and secrete the missing protein, which diffuses locally and supplies the genetically deficient host cells (► Fig. 7.1).¹³

NSCs are capable of differentiating in situ into the three major cell lineages of the mature CNS: neurons, astrocytes, and oligodendroglia⁷⁸ (► Fig. 7.2). The most sophisticated and technically challenging use of SC therapy for CNS diseases will be replacement of damaged neuronal circuits and glial architecture based on these regenerative and pluripotent properties. Cross-correction models, however, do not require lineage-specific differentiation or circuitry repair.

7.3.1 Cellular Delivery

Various methods for delivery of SCs to their therapeutic target have been employed, including IV, intra-arterial (IA), and direct surgical implantation. IV administration of SCs is less invasive than either IA or direct surgical implantation, but delivery of cells to the CNS is significantly hindered by a pulmonary first-pass effect,⁷⁹ with only approximately 4% of cells entering the brain.⁸⁰ Up to 21% of cells injected into the internal carotid artery enter the brain,⁸¹ but this technique may be complicated by the occurrence of microemboli.⁸² Direct intracerebral transplantation followed by intraventricular and IV transplantation results in the greatest number of SCs at the site of a CNS lesion.⁸³ However, functional recovery does not necessarily correlate with the absolute number of viable transplanted cells into the targeted area.⁸⁴

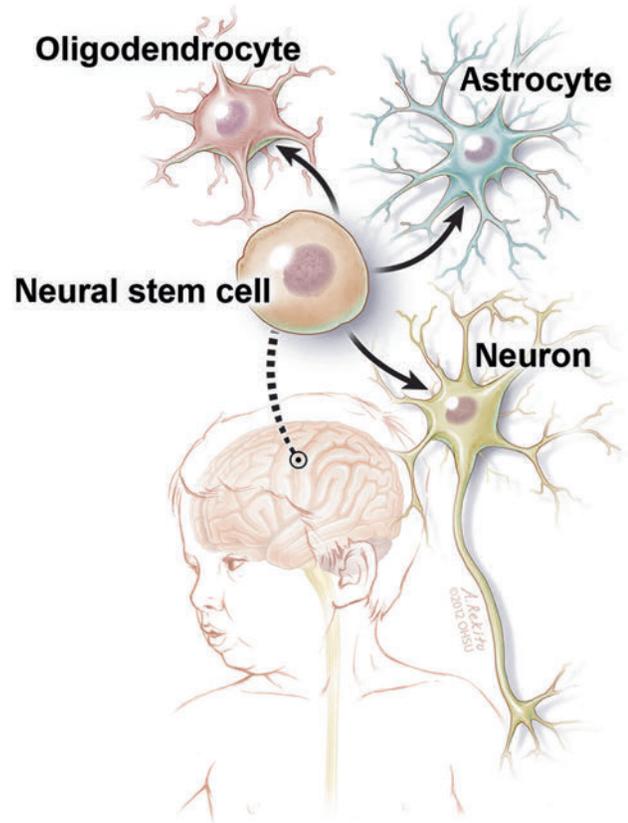

Fig. 7.2 Schematic diagram of an intracerebrally transplanted neural stem cell's capability to differentiate into an oligodendrocyte, astrocyte, or neuron.

Implanted SCs have the ability to improve neurologic outcomes without crossing the BBB. In several preclinical stroke models, neurologic function improved despite that fact that few or no SCs were found in the brain.^{80,85} This is likely due to the ability of NSCs to counteract inflammatory cytokines, toxic metabolites, free radicals, and excitotoxins released systemically after an insult.⁸⁶ NSCs also produce multiple protective factors such as glial cell line-derived neurotrophic factor (GDNF), which may contribute to rescuing dopaminergic neurons in PD¹ and improving functional outcomes after stroke,⁸⁷ as well as glial and neural growth factors, such as neurotrophin-3 (NT-3) and ErbB-2, respectively.^{88,89} Other neuroprotective factors enhanced by NSCs include fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), bone-derived neurotrophic factor (BDNF), nerve growth factor, and ciliary neurotrophic factor.^{87,90}

7.3.2 Disease States

Ischemia

Cerebral ischemia from moyamoya disease, genetic disorders, and perinatal thromboembolic disease results in profound morbidity in the pediatric population. Cerebral ischemia triggers the proliferation of NPCs in the SVZ^{91,92} and dentate gyrus. NPCs migrate to areas of focal ischemia in rodent models.^{93,94} SVZ cells may have the capacity to regenerate some striatal

neurons following ischemia.⁹⁵ Migration of NSCs to the site of ischemic injury is activated by erythropoietin.^{93,96,97} Epidermal growth factor receptor (EGFR) levels in the SVZ increase following cerebral ischemia, while infusion of EGF into ischemic brain increases the number of EGFR-positive neuroblast precursors,⁹⁵ which migrate into the striatum and cerebral cortex following ischemic insults to those regions.^{93,98} Although the therapeutic implications of these findings remain unclear, it appears that SVZ and other stem and progenitor cells demonstrate tropism toward sites of CNS injury.

For neuronal circuit repair after stroke, implanted SCs must migrate to appropriate targets and also differentiate into appropriate cell types. In a rodent ischemia model, implanted ESC-derived NPCs differentiated into neurons and glia with electrophysiologic function.⁹⁹ Similarly, transplanted NSCs in a gerbil model of ischemia yielded NeuN-positive neurons and glial fibrillary acidic protein (GFAP)-positive glia, grew synaptic connections between host and graft tissue, and improved neurologic function.¹⁰⁰ After intraventricular injection, NSCs in a mouse model of neonatal hypoxic-ischemic encephalopathy migrated to the site of ischemic injury and differentiated into neurons, resulting in improved memory and learning compared to controls 8 months after transplantation.¹⁰¹ Intracerebral transplantation of NSCs in a rodent model of cerebral palsy (CP) yielded a 5% population of NSC-derived neurons in the infarction cavity.¹⁰² At the time of this writing, there were no published clinical trials of SC therapy for CP; however, two clinical trials have been completed, and three trials are currently recruiting patients.¹⁰³ When the NSC neurons were transduced with a retroviral neurotrophin (NT-3) before transplantation, the proportion of NSC-derived neurons in the infarction cavity increased to 20% and in the penumbra to 80%, raising the possibility that these therapies interact synergistically. In other studies, IA^{104,105} or IV⁸⁴ SC injection to treat stroke has also improved neurologic recovery.⁸⁴

Human studies support the potential of SC therapy for the treatment cerebrovascular accidents (CVAs). Human neuronal cells implanted into 14 adult patients with ischemic or hemorrhagic CVA were associated with improved activities of daily living and memory compared to baseline, but not compared to nonimplanted controls.¹⁰⁶ No significant change was noted in European Stroke Scale motor score. In one patient, who expired 27 months after transplantation, human neuronal cells were found adjacent to the lacunar infarct.¹⁰⁷ Another clinical study of intracranial implantation of fetal porcine cells for stroke therapy was terminated by the U.S. Food and Drug Administration (FDA) after enrolling only five patients because of the occurrence of adverse events, including worsened motor deficits and seizure onset following transplantation.¹⁰⁸

SCs may play different roles in stroke therapy depending on the timing and route of administration. SC administration very early after ischemic stroke may provide neuroprotection of salvageable penumbra by increasing neuronal proliferation and abating edema,^{102,109} although the proportion of SCs surviving transplantation is relatively low.^{76,110} By contrast, SCs administered peripherally 21 days after ischemic injury survive in greater numbers and differentiate via neuronal and glial lineages within injured brain.¹¹¹

Tumors

Currently, the most common application of SC therapy in children is high-dose chemotherapy (bone marrow-ablative) with autologous hematopoietic SC transplant rescue as a salvage therapy for recurrent or high-risk brain tumors. The most common source of SCs is peripheral blood, followed by bone marrow. This treatment has been used in a variety of neoplasms, including medulloblastoma, malignant glioma,¹¹² ependymoma, germ cell tumors, and atypical rhabdoid teratoid tumors.¹¹³ Responses are variable (0 to 75% long-term survival) and often at the price of substantial toxicity, including death in up to 33%, mucositis, neutropenia, and renal and hepatic failure.¹¹³ There are currently approximately 40 registered SC-based clinical trials worldwide for pediatric brain tumors, which will continue to define the safety and efficacy of this treatment strategy over time.¹¹⁴

Brainstem gliomas and supratentorial malignant gliomas constitute approximately 15%¹¹⁵ and up to 10%,¹¹⁶ respectively, of pediatric brain tumors. Neural SCs appear to have a high affinity, or tropism, for brain tumor tissue, making them ideal vehicles for the introduction of therapeutic enzymes and chemotherapy.^{113,114} Bone marrow-, adipose tissue-, and umbilical cord-derived SCs all show tropism for brain tumor tissue, with comparable rates of SC survival and percentage of migratory cells.¹¹⁵ Tumors attract SCs via the secretion of numerous chemoattractant factors, including cytokines, VEGF, stromal cell-derived factor-1 (SDF-1), NT-3, TGF- β_1 , and interleukin-8 (IL-8).^{114,117}

Interleukin-4 (IL-4) cDNA delivered via SCs in a rodent model of malignant glioma resulted in tumor regression, as determined by magnetic resonance (MR) imaging, and significantly improved survival.¹¹⁸ In this study, treatment with unaltered NSCs alone also provided a degree of intrinsic antitumor activity. In another study, BMSCs expressing interferon- γ (IFN- γ) increased survival in a model of supratentorial malignant glioma.⁷⁷

Mesenchymal SCs (MSCs) have also successfully delivered prodrug converting enzymes in animal models of brainstem glioma. As a proof of concept, human NSCs engineered to express cytosine deaminase, a prodrug enzyme, and IFN- γ , an antiangiogenic and immune response enhancer, migrated, increased tumor cell apoptosis, and substantially reduced tumor volume in a model of brainstem glioma.¹¹⁵ Human adipose tissue-derived MSCs genetically altered to convert the prodrug of irinotecan, a topoisomerase-1 inhibitor, into the active form significantly extended the survival of rats treated with both the engineered MSCs and irinotecan.¹¹⁹ This strategy is also being tested in human clinical trials. Genetically modified NSCs expressing an enzyme for the conversion of 5-fluorocytosine (5-FC) to 5-fluorouracil (5-FU) are being evaluated for the treatment of recurrent high-grade gliomas.¹²⁰

NSCs also show substantial tropism toward medulloblastoma. Even when injected in the contralateral hemisphere in an animal model, human NSCs engineered to convert systemic 5-FC to 5-FU reduced the size of medulloblastoma tumors by 76%.¹²¹ In another model, human NSCs engineered to convert irinotecan to its active form reduced the growth rate of cerebellar tumors.¹²²

Lysosomal Storage Disorders

The LSDs are a class of over 40 disorders,¹²³ each defined by "... a specific inherited enzyme deficiency that leads to accumulation of complex macromolecules, such as sphingolipids, glycogen, mucopolysaccharides, and glycoproteins in lysosome[s]," ultimately resulting in neuronal death.⁶⁴ Many of the LSDs have their most devastating effects on the CNS. Because of this, the transmission of peripherally delivered therapies, such as enzyme replacement, across the BBB has posed a significant impediment to therapy. For many LSDs, which are often severely morbid or fatal, there is no effective treatment. SC therapy for LSD offers the potential to deliver replacement enzymes in a sustainable fashion within the CNS by using a cross-correction model.

Intraventricular delivery of enzyme, although technically challenging, can positively impact some LSDs. In rodent models of the GM2 gangliosidosis (Tay-Sachs disease and Sandhoff disease), intraventricular injection of recombinant human HexA (Om4HexA) with a high mannose-6-phosphate (M6P)-type-N-glycan content reduced levels of sphingolipids, GM2, and asialo-GM2 (GA2) in brain parenchyma and improved both motor function and survival.¹²⁴

SCs may provide continuous and potentially durable enzyme replacement for LSDs. To date, however, the clinical benefits of SC therapy for LSD have been mixed, and success in preclinical models has not necessarily translated to patients. In a rodent model of Niemann-Pick disease, NSCs implanted into the cerebellum increased survival but did not affect weight loss or neurologic function.¹²⁵ A number of animal studies in which multiple treatment methods were used in a single animal, such as BMSC transplantation and ERT, have shown outcomes superior to those obtained when either therapy was used individually.¹²⁶ Multimodality therapy may also prove useful in human patients.

MSCs delivered to 12 patients with metachromatic leukodystrophy or Hurler syndrome did not improve cognitive or physical development.¹²⁷ UCB transplantation in 25 infants with Krabbe disease improved neurocognitive function and development in those patients who were asymptomatic at the time of transplant.¹²⁸ Similar results were found after UCB for X-linked adrenoleukodystrophy (X-ALD).¹²⁹ Hematopoietic SC transplantation is therefore currently advised for use only in asymptomatic patients, creating a premium for the early perinatal diagnosis of inborn errors of metabolism.⁵⁷

Intracerebral transplantation of human NSCs in a rodent knockout model of infantile NCL resulted in SC engraftment, migration, production of the missing palmitoyl-protein thioesterase 1 (PPT1) enzyme, reduced burden of autofluorescent material, and neuronal preservation in cortex and hippocampus.⁷⁸ Based on these results, a Phase I trial of intracerebral transplantation of human NSCs for infantile NCL and late infantile NCL was recently completed. This study utilized multiple intracerebral and bilateral intraventricular surgical implantations (► Fig. 7.3) of very high volumes of SC suspension, with a total dose of SC delivery unprecedented in previous human therapy (up to 1 billion cells per patient). The trial also represented the first human treatment with a purified and characterized NSC, the first human CNS implantation of a purified SC population, and the first surgical CNS transplantation carried out in chil-

dren.^{130,131} Six children underwent transplantation and were treated with 1 year of immunosuppression. No surgical, SC-related, or immunosuppressive toxicity was observed, and human leukocyte antigen (HLA) antigenic evidence suggested successful engraftment and migration more than 2 years after transplantation and well after the cessation of immunosuppression. The study was not powered to assess efficacy.¹³⁰

Traumatic Brain Injury

Traumatic brain injury is responsible for nearly 500,000 emergency department visits each year by children ages 0 to 14 years.¹³² Mortality and morbidity from severe traumatic brain injury have not improved dramatically over the past 30 years, suggesting the need for novel treatment strategies for neuroprotection after primary brain injury and for neuro-restoration.^{133,134} SC therapy has the potential to deliver these benefits to patients with traumatic brain injury.

Injured brain parenchyma expresses an abundance of inflammatory mediators, creating a hostile host environment for transplanted SCs. Implanted SC viability correlates with the degree of injury.¹³⁵ As in stroke, SC administration is most likely optimal immediately following the injury, before the peak inflammatory response, or after the acute inflammatory process has subsided.⁸²

Bone marrow-derived SCs administered intracerebrally,¹³⁶ IV,^{50,137} or IA¹³⁸ after traumatic brain injury all survived for up to 3 months and migrated to the injury site. NSCs have also been found to migrate to injury sites and are associated with improved neurologic function, surviving up to 14 months.^{82,139} UCB administered after traumatic brain injury contains SCs that differentiate into neurons and astrocytes and result in improved function.¹⁴⁰

In a preliminary study, 10 children with severe traumatic brain injury received IV autologous bone marrow-derived mononuclear cells within 48 hours of injury.¹⁴¹ This feasibility study found no evidence of treatment-related CNS or systemic toxicity but was not designed to assess neurologic or cognitive functioning.

Epilepsy

An increasing amount of preclinical research has focused on using NSCs to treat mesial temporal lobe epilepsy and, to a lesser degree, epilepsy related to cortical dysplasia. The microenvironment of the epileptogenic hippocampus is favorable to the implantation and integration of SCs.¹⁴² Lack of inhibition at the dentate hilus allows the propagation of ictal discharges from the entorhinal cortex to the hippocampus and subsequently the rest of the brain.¹⁴³ One strategy used for the treatment of refractory epilepsy is therefore transplantation of inhibitory NSCs.¹⁴⁴ The dentate gyrus may be the most appropriate target for inhibitory precursor transplantation. Other treatment strategies using SCs for epilepsy include promotion of surround inhibition and neuronal replacement.¹⁴⁵

Transplanted SCs require differentiation of NSCs into inhibitory neurons—for example, those utilizing γ -amino butyric acid (GABA) neurotransmission—to cause mesial temporal inhibition. NSCs implanted into the dentate gyri of rats produce GABA-ergic cells, raise seizure thresholds, and shorten seizure duration.¹⁴⁶ Transplanted embryonic medial ganglionic eminence cells engraft and migrate in large proportions to the hippocampus, striatum, and neocortex in animal models of partial and generalized epilepsy, with prolonged survival.^{147–150} Transplanted cells also influence host neuronal circuitry by increasing levels of synaptic inhibition in neocortical pyramidal neurons.¹⁴⁷ Loss of inhibitory interneurons likely also plays an important role in the pathogenesis of cortical dysplasia, which may represent a potential target for NSC-derived inhibitory neuron transplantation.^{151,152}

Cellular therapy could also reduce seizures in mesial temporal lobe epilepsy by replacing dysfunctional or damaged neurons. NPCs implanted into the cerebral cortex and hippocampus of rats develop projections to the host thalamus and contralateral hippocampus, generate action potentials, and harbor N-methyl-D-aspartate (NMDA)-mediated excitatory and GABA-mediated inhibitory postsynaptic currents.^{153,154}

Spinal Cord Injury

Like the brain, the zone adjacent to the spinal cord ependymal lining is a key site in for NSC formation and proliferation after injury.^{155,156} The host environment at the site of spinal cord injury is important to potentiate SC-induced recovery. Following the clearance of necrotic debris, gliotic scarring inhibits the regeneration of severed axons.¹⁵⁷ Implantation of selected macrophages may play a role in preventing a glial scar, clearing cellular debris, and promoting the migration of endogenous SCs to the site of injury.¹⁵⁸ Recovery of motor function in an animal model is significantly increased when SC transplants and neurotrophins are administered 2 to 4 weeks following spinal cord transection compared to those administered more acutely, in the presence of deleterious, acute inflammatory responses to injury,¹⁵⁹ including such mediators as tumor necrosis factor- α (TNF- α), IFN- γ , and IL- β ₁.¹⁶⁰

In animal models, direct implantation of SC into the injured spinal cord dramatically improves function.^{161,162} NSCs engrafted into the injured cord tend to stay confined to the white

matter and differentiate into glial cells,¹⁶³ particularly oligodendrocytes that form myelin.¹⁶⁴ Nevertheless, those NSCs that differentiate into astrocytes¹⁶⁵ and neurons¹⁶⁶ also have the potential to improve neurological function. Implantation of UCB into the injured spinal cord has also produced myelin¹⁶⁷ and improved neurological function.¹⁶⁸

In a Phase I clinical trial,¹⁶⁹ the injection of autologous macrophages into the spinal cords of eight patients with complete spinal cord injury was associated with recovery in three patients from American Spinal Injury Association Impairment Scale grade A to grade C. Phase II studies are currently under way utilizing this technique.¹⁷⁰ Patients with both subacute and chronic spinal cord injury treated with BMSCs showed modest functional improvements, particularly when cells were injected into the vertebral artery.¹⁷¹ PNCs of fetal origin were directly injected at the site of injury in patients with postinjury syringomyelia without adverse events and with MR imaging correlates of successful engraftment.¹⁷²

7.4 Challenges to Cellular Therapy

7.4.1 Biological Challenges

Immunocompatibility

ESCs differ genetically from recipients but express little HLA class I and no class II.¹⁷³ As ESCs differentiate, class I major histocompatibility complex is upregulated, so that immunosuppressant therapy is required after transplantation.¹⁷⁴ Alternatively, it may be possible by using nuclear transfer or other techniques to create donor ESCs genetically identical to the recipient.^{175,176} The use of immune-inert, semipermeable capsules to house SCs may also promote immunocompatibility and protect SCs from attack by inflammatory modulators resulting from direct cerebral implantation.¹³¹

The proper dose, timing, and duration of immunosuppression after CNS SC transplantation are controversial, especially given the medical fragility of the population of patients for whom SC therapy is currently being explored. In two studies of transplantation of human fetal mesencephalic tissue for PD, one study used immunosuppression and the other did not.^{30,31} Grafted cells were present on postmortem histology from patients in both studies, although an activated macrophage marker (CD45) was increased around SC graft injection sites in nonimmunosuppressed patients.³⁰ In a Phase I trial of human NSC transplantation for NCL, patients were treated with immunosuppression just before and for 1 year after implantation. Frequent medication adjustments were required because of the interaction of anticonvulsant and immunosuppressant drugs, but there were no obvious additional adverse effects. Evidence for persistent engraftment was present in two of three postmortem examinations, in one case more than 2 years after transplantation.¹³⁰ In a single patient with stroke in whom human neuronal cells derived from a teratocarcinoma line were implanted and who received peritransplantation immunosuppression for 9 weeks, the implanted neurons survived for more than 2 years.¹⁰⁷

Neoplastic Potential

ESCs have many similarities to neoplastic cells, including the ability to undergo unlimited, undifferentiated proliferation and to form tumors in animal models of PD.^{15,16} ESCs readily differentiate into all three germ layers and have a propensity to form teratomas. Cell overgrowth^{14,17} and metastatic retinoblastoma formation have also been observed in animal models.¹⁷⁷ To reduce their oncologic potential, ESCs must be used in lineage-specific, differentiated form, such as NSCs. However, brain tumor formation was reported in a human patient 4 years following implantation of fetal NSCs.¹⁷⁸ Pluripotent SCs may be sorted according to their identifying cell surface proteins¹³ or by leveraging cell type-specific transcription factors.¹⁷⁹

Other Biological Obstacles

Scientists and clinicians must overcome several additional obstacles before SC therapy can be widely used in the treatment of pediatric neurologic disorders. First, there is currently a lack of clinical markers that specifically identify transplanted NSCs in order to distinguish them from other progenitor or differentiated host cells.^{1,2} Second, therapeutic strategies must mitigate host factors. For example, direct intracerebral implantation may affect the viability and functionality of SCs because of the creation of a hostile inflammatory microenvironment.^{30,31,106,108,130} The underlying disease state may additionally result in gliosis or vacuolization that can adversely affect engraftment, migration, or the function of transplanted SCs. Third, in many disorders, particularly developmentally relevant disorders in childhood, outcomes assessment may be confounded by a lack of appropriate and validated instruments. For example, most validated measures of neurocognition require intact visual and motor functional skills, which are often damaged early (e.g., in LSDs).¹³¹ Fourth, it is difficult to track the location and assess the viability of implanted SCs in human patients. Guzman and colleagues used iron nanoparticles to successfully trace migration patterns as assessed by MR imaging and histology.¹⁸⁰ Notably, these iron nanoparticles did not affect cellular migration, survival, differentiation, or electrophysiologic characteristics. This technology has the potential to identify single cells.¹⁸¹ Others have successfully employed MR spectroscopy¹⁸² and positron emission tomography (PET)^{183,184} to identify NPCs in humans. Engineering of SCs to facilitate *in vivo* imaging, however, creates additional regulatory hurdles for their use in human trials.

7.4.2 Regulatory and Ethical Challenges

The regulatory issues surrounding SC transplantation are complex and continue to evolve. In the United States, the FDA oversees the use of SCs and other biological therapeutics in human patients. Because they are human cells that are highly processed and “utilized for other than their normal function,”^{185,186} SCs must conform to both Section 351 regarding biological products¹⁸⁷ and Section 361 regarding human cells and associated products¹⁸⁸ of the Public Health Service Act.¹⁸⁵ The U.S. Code of Federal Regulations (CFR) Part 1271 details the regulation of “human cells, tissues, and cellular and tissue-based prod-

ucts.”¹⁸⁶ Generally, this code was designed to “create a unified registration and listing system for establishments that manufacture human cells, tissues, and cellular and tissue-based products (HCT/Ps) and to establish donor eligibility, current good tissue practice, and other procedures to prevent the introduction, transmission, and spread of communicable diseases by HCT/Ps.”¹⁸⁶ Thus, the regulatory standards and checks for the manufacturing of biological material for human use are stringent and expensive.¹⁸⁵

SC research faces additional serious challenges related to ethical concerns about the creation and use of human embryonic and other cellular tissue. Both sides in this debate cite concern regarding the value of human life as a motivating factor. Proponents of SC therapy identify concern for patients with severe or fatal, untreatable nervous system diseases as a factor justifying this work. Opponents cite concern that embryonic tissue, representing human life, will be arbitrarily created or destroyed for the purposes of SC therapy. In both cases, sincerely held views deserve the attention and respect of the medical and scientific communities.¹⁸⁹

The ethical attention of the public and press has focused to a large degree on ESC transplantation.^{190,191} In many cases, however, lineage-specific, or “adult,” SCs are actually sourced from fetal tissue. As discussed previously, SCNT and iPSC technology may in future provide a relatively ethically neutral source of human SCs for therapeutic purposes.

The public focus of attention on the ethics of ESC transplantation has diverted necessary attention from a number of other important considerations: Who should own the intellectual property and biological material rights for cells necessary for human therapy? Is the use of “sham” surgery in human clinical trials of cellular transplantation ethical?³¹ What are the boundaries for the appropriate use of complex and expensive transplantation therapy (particularly in cases in which such therapy may be only palliative)? How can we guard the interests of children and neurocognitively disabled patients enrolled in trials of SC therapy, without entirely denying their access to such therapies and preventing progress in the treatment of their diseases? Because of these and other questions, progress in human SC therapy must occur within the bounds of careful and public regulatory oversight and ethical guidelines.¹⁸⁹

7.5 Summary

Stem cells are inherently capable of self-replication and expansion, engraftment, long-term survival in a host environment, and extensive migration. In various circumstances, they can be used to supply missing proteins, provide neuroprotection and trophic support to host cells, or even reconstruct missing or damaged neural architecture.

Significant challenges to successful human therapy with SCs remain, including overcoming barriers to CNS administration, modulating the host environment and immune response, and accomplishing *in vivo* the tracking of transplanted SCs. Recent scientific developments hold promise for mitigating ethical concerns about and practical limitations on sources of SCs for human therapy.

Pearls

- A variety of SCs are available for potential use in human therapy, including totipotent embryonic cells and pluripotent, or lineage-specific, “adult” SCs.
- SCs for CNS therapy may be delivered with transvascular, intrathecal, or direct surgical transplantation strategies, or a combination of these, depending on disease state, cell line, and transplantation goals.
- Mitigation of negative host factors, immunosuppression, and in vivo cellular tracking represent ongoing challenges in human SC therapy.
- Significant ethical and regulatory challenges to SC therapy deserve the careful attention of all clinicians involved in investigational SC therapy.

8 Neurogenetic Basis of Pediatric Neurosurgical Conditions

Claudia C. Faria, Yuzo Terakawa, and James T. Rutka

In the past decade, significant progress has been made in increasing our understanding of the molecular genetic basis of neurosurgical disorders. As an example, an integrative genomics approach to a large cohort of medulloblastomas has shown that these tumors comprise four separate molecular subgroups with distinct demographics, clinical presentations, transcriptional profiles, genetic abnormalities, and clinical outcomes.¹ Furthermore, a genome-wide association study has recently identified the first susceptibility gene for moyamoya disease.² Although the molecular basis of pediatric neurosurgical diseases has not been fully elucidated, the application of advanced techniques in molecular biology to the research of neurosurgical diseases is contributing to our understanding of the molecular basis underlying pediatric neurosurgical conditions. In this chapter, we summarize the genetic basis of neurosurgical conditions like neoplasms, cerebrovascular diseases, and congenital and developmental disorders, especially focusing on common pediatric neurosurgical diseases.

8.1 Neurogenetic Basis of Common Pediatric Neurosurgical Diseases

8.1.1 Neoplasms

Diffuse Astrocytoma

Pediatric astrocytomas are histologically similar to adult astrocytomas; however, the extent to which the molecular pathogenesis of adult astrocytomas is similar to that of pediatric astrocytomas is unclear. Indeed, previous cytogenetic studies of high-grade pediatric astrocytomas in which comparative genomic hybridization (CGH) or fluorescence in situ hybridization (FISH) was used have demonstrated distinct patterns of copy number alterations from adult astrocytomas³ and infrequent copy number alterations in pediatric astrocytomas as opposed to those frequently seen in adult astrocytomas.^{4,5} More recently, advanced microarray-based genetic approaches have also been used to investigate pediatric astrocytomas. Genome-wide profiling with single-nucleotide polymorphism (SNP) arrays performed in 18 pediatric and 6 adult cases of glioblastoma multiforme (GBM) suggested that pediatric and adult GBMs are two molecularly distinct diseases, even though they have a few copy number alterations in common.⁶ Similarly, SNP arrays that interrogated copy number alterations in 78 pediatric high-grade gliomas have revealed significant differences in copy number alterations between pediatric and adult GBMs,⁷ suggesting that pediatric astrocytomas show distinct biological behavior and most likely have a different molecular pathogenesis.

Although amplification of the epidermal growth factor receptor (*EGFR*) gene is seen in up to 40% of adult glioblastomas and 15% of adult anaplastic astrocytomas, it is not commonly seen in pediatric astrocytomas.⁸ Nevertheless, high expression levels of *EGFR* were found by immunohistochemistry in 80% of pediatric non-brainstem high-grade gliomas. Mutations of the

PTEN gene at the 10q23 locus are rare in pediatric high-grade astrocytomas,⁹ but significant correlations between the presence of *PTEN* mutation and decreased survival have been demonstrated in high-grade pediatric astrocytomas. Moreover, frequent heterozygous deletions of 10q23 have been shown by FISH in 61% of 44 pediatric GBMs, and those cases harboring 10q23 deletions were associated with a significantly shorter overall survival time.¹⁰ Mutations of *p53* in pediatric high-grade astrocytomas have been reported in fewer than approximately 40% of cases.⁹ Overexpression of *p53* as determined by immunohistochemistry is strongly associated with an adverse outcome in pediatric gliomas.¹¹ In one series of 29 high-grade pediatric astrocytomas, inactivation of the *p53/MDM2/p14ARF* pathway by mutation of *p53*, overexpression of *MDM2*, or deletion of *p14ARF* was seen in over 95% of the cases, whereas the *pRb/cyclin D1/CDK4/p16* pathway was inactivated only in up to 25%, as opposed to over 80% of the corresponding adult tumors.⁸

Diffuse intrinsic pontine glioma (DIPG) is another entity of diffuse astrocytomas most often seen in the pediatric population; however, relatively little is known about the molecular genetics underlying DIPGs, probably because of a lack of availability of primary surgical specimens. A previous study has found a particularly high rate of *p53* mutations (71%) in seven pediatric DIPG cases. Another study has demonstrated *EGFR* overexpression and/or *EGFR* amplifications in 14 of 16 high-grade DIPGs, whereas only two of 12 low-grade DIPGs exhibited a low level of *EGFR* expression.¹² More recently, the role of two other genes—namely, *PDGFRA* and poly (ADP-ribose) polymerase-1 (*PARP1*)—has been implicated in DIPGs with the use of comprehensive SNP microarrays.^{7,13}

Pilocytic Astrocytoma

Early cytogenetic studies by CGH failed to demonstrate common cytogenetic aberrations in pilocytic astrocytomas, revealing few abnormalities in general. Among the few aberrations, gain of chromosome 7 was one of the most common events seen in pediatric pilocytic astrocytomas. Cytogenetic abnormalities were seen more commonly in patients older than 15 years than in patients younger than 15 years,¹⁴ and adult cases had much more complex karyotypes, with multiple areas of gains and losses. One of the most important studies in pilocytic astrocytomas during the past decade was an array-based CGH study that identified gains of the *BRAF* locus at the 7q34 locus.¹⁵ In this study, a tandem duplication of the *BRAF* locus was seen in 28 cases and p.V600E activating point mutations of *BRAF* in three cases of 53 pilocytic astrocytomas, demonstrating the potentially important role of *BRAF* and subsequent activation of the mitogen-activated protein kinase (MAPK) signaling pathway in pilocytic astrocytoma pathogenesis. Further molecular mechanisms with regard to the *BRAF* gene and MAPK pathway activation have recently been described.^{16–18} The incidence of *p53* mutations in pilocytic astrocytomas is controversial, with some authors reporting only infrequent *p53* mutations, whereas other authors report more frequent mutations. Mutations

of *PTEN* have rarely been reported in pilocytic astrocytomas. Protein expression of *p16*, *CDK4*, and *PTEN* was detected in 73%, 61%, and 38% of pilocytic astrocytomas, respectively.¹⁹

Medulloblastoma

Medulloblastoma has been reported in the setting of several different hereditary cancer syndromes, including Li-Fraumeni syndrome, Gorlin syndrome, Turcot syndrome, and Rubinstein-Taybi syndrome.²⁰ The Li-Fraumeni syndrome is associated with germline mutations in the *p53* gene. Patients with Li-Fraumeni syndrome have an increased risk for the development of embryonal tumors (including medulloblastoma) and choroid plexus carcinoma, among many other cancers. Patients with Gorlin syndrome (nevroid basal cell carcinoma syndrome) have germline mutations in the *PTCH1* gene, a component of the sonic hedgehog (SHH) signaling pathway, and up to a 5% risk for developing medulloblastoma. Germline mutations in the *SUFU* gene, a downstream mediator of the SHH pathway, have also been shown in patients with medulloblastoma.²¹ Germline mutations of the *APC* gene, a component of the Wnt signaling pathway, are seen in patients with Turcot syndrome, who have an increased risk for colorectal carcinoma and brain tumors, predominantly medulloblastoma. Children with Rubinstein-Taybi syndrome have a complex developmental disorder that includes broad thumbs and toes, characteristic facies, severe developmental delay, and a predisposition to malignancy, including medulloblastoma, oligodendroglioma, and meningioma. This syndrome is secondary to deletion/mutation of the Creb binding protein gene (*CBP*), which functions in three pathways involved in medulloblastoma pathogenesis (SHH, Wnt, and *p53*).²²

The most common cytogenetic changes observed in medulloblastoma are loss of chromosome 17p, often through the formation of an isochromosome 17q (loss of one copy of the short arm and gain of one copy of the long arm) and gain of chromosome 7. Other chromosomes frequently found to be lost are 6, 8p, 9q, 10q, 11 and 16q. Genes frequently amplified and/or overexpressed include *MYC*, *ERBB2*, *OTX2*, *PDGFRA*, and *CDK6*.²³

Recently, large genomic analyses have shed some light into the genetic landscape of medulloblastoma and allowed its stratification into molecular subgroups (► Fig. 8.1). Four independent studies used integrated genomics and established the existence of a Wnt subgroup, an SHH subgroup, and multiple non-Wnt/SHH subgroups. A recent working committee renamed these last subgroups as group 3 and group 4 medulloblastomas, which are currently still poorly understood.²⁴ The Wnt subgroup has a very good prognosis, with long-term survival rates exceeding 90%. The most common genetic alterations found are *CTNNB1* mutations and monosomy 6. SHH medulloblastomas have changes in components of the SHH pathway, such as somatic mutations of *PTCH*, *SMO*, and *SUFU* and amplifications of *GLI1* and *GLI2*. This subgroup is more common in young children and in adults, who have an intermediate prognosis between that of the Wnt subgroup (very good) and that of group 3 (poor). Group 3 is characterized by frequent amplifications of *MYC* and by changes in genes involved in the photoreceptor or GABAergic (γ -aminobutyric acid) signaling. Patients in this group have a high incidence of metastasis and a dismal prognosis. The most common cytogenetic alterations seen in group 4 medulloblastomas are isochromosome 17q (66%) and loss of

Ependymoma

There are few known familial ependymoma syndromes. Spinal intramedullary ependymomas are frequently diagnosed in individuals with neurofibromatosis type 2 (NF2) and are one classic manifestation of the disease. Ependymomas have also been reported in patients with Turcot syndrome (colonic neoplasia and central nervous system neoplasia). These individuals have germline mutations in the *APC* gene on chromosome 5. Ependymomas have been reported in individuals with multiple endocrine neoplasia type I (MEN1) secondary to mutation of a tumor suppressor gene on chromosome 11q13. Rare families where multiple individuals have ependymomas in the absence of other known germline mutation syndromes have been described.

Over the years, numerous chromosomal abnormalities were reported in ependymoma by studies using karyotyping and CGH. Common genetic anomalies include loss of chromosome 1p, 3, 6q, 9p, 10q, 13q, 16p, 17, 21, and 22q as well as gains of 1q, 4q, 5, 7, 8, 9, 12q, and 20.²⁵ The most common losses seen in children were loss of chromosome 6q, followed by 22q. The regions most frequently amplified in pediatric ependymoma are chromosomes 1q and 9. Gains of 1q are associated with posterior fossa ependymomas, anaplastic features and unfavorable outcome.²⁶

With advances in microarray technology, copy number variations could be mapped at much higher resolutions. Using array

CGH, Taylor *et al.* profiled 103 ependymomas and found three molecularly distinct subgroups, correlated with the anatomical location of the tumor in the supratentorial, posterior fossa, or spinal compartments.²⁷

Similar to array CGH, gene expression profiling studies were able to distinguish tumor-specific signatures according to anatomical location.^{27,28} Supratentorial ependymomas had high expression levels of *EPHB-EPHRIN* (*EPHB2/3/4* and *EPHRINA3/4*), *NOTCH* (*JAGGED1/2*), and genes involved in cell cycle regulation (*CYCLINB2/D1/G2*, *CDK2/4*, and *CDKN1C/2C*). Posterior fossa tumors highly expressed genes inhibitors of differentiation (*ID1/2/4*) and members of the aquaporin family (*AQP1/3/4*). Finally, spinal ependymomas showed up-regulation of various homeobox genes (*HOXA7/9*, *HOXB6/7* and *HOXC6/10*) and insulin-like growth factor 1 (*IGF1*). More recently, Witt *et al.* transcriptionally profiled two large independent cohorts of posterior fossa ependymomas and identified two clinically and molecularly distinct subgroups.²⁹ Group A patients were younger, with tumors located laterally in the cerebellum, and with a balanced genome. This subgroup was also associated with worse clinical outcome and higher incidence of metastasis and recurrence (► Fig. 8.2). In contrast, Group B patients had tumors in the midline and a better prognosis. The candidate marker genes to distinguish the two groups were upregulation of *LAMA2* in Group A and *NELL2* in Group B.²⁹

Other genetic abnormalities were described in ependymomas, including focal amplifications of *MYCN*, *EGFR* and *YAP1* and deletion of *CDKN2A* and *SULT4A1*. The interesting finding from these studies is that up to 40% of pediatric ependymomas appear to have a balanced genomic profile raising the possibility that epigenetic mechanisms may play an important role in ependymoma pathogenesis.

Atypical Teratoid/Rhabdoid Tumors

Atypical teratoid/rhabdoid tumors (AT/RTs) are aggressive embryonic tumors that are usually diagnosed in children younger than 2 years (► Fig. 8.3). They are frequently misdiagnosed as medulloblastoma/primitive neuroectodermal tumor

(PNET), especially on small biopsies, as up to 70% of rhabdoid tumors contain fields of cells indistinguishable from PNET. As well as occurring in the central nervous system (CNS), rhabdoid tumors are also seen in the kidneys and less commonly in a variety of locations in the soft tissues. Versteeg and colleagues identified the tumor suppressor gene on chromosome 22q11 as the *SMARCB1* gene, also called *hSNF5/INI1*.³⁰ The *SMARCB1* gene was biallelically inactivated by deletions and/or truncating mutations in a series of renal rhabdoid tumors and cell lines, suggesting that it acts as a classic tumor suppressor gene. This was confirmed by the reintroduction of the gene to cell lines from

AT/RTs deficient in *SMARCB1*, which resulted in dramatic cessation of growth, cell cycle arrest, apoptosis, and expression of markers of cell senescence.³¹

Biegel and co-investigators went on to show somatic deletions and/or truncating mutations of *SMARCB1* in CNS rhabdoid tumors.³² It was shown that some children with rhabdoid tumors have de novo germline mutations of *SMARCB1*, suggesting that these children were born with “one hit” in the *SMARCB1* gene and were predisposed to develop rhabdoid tumors.³² In some rare families with an elevated incidence of rhabdoid tumors and/or choroid plexus carcinomas, there may be an inherited germline mutation of the *SMARCB1* gene that predisposes affected family members to cancer.²⁰ At least 80% of AT/RTs have genomic mutations of the *SMARCB1* gene. Of the remaining 20%, many have decreased expression of *SMARCB1* at the protein or RNA level.

The *SMARCB1* protein is a member of the SWI/SNF adenosine triphosphate (ATP)-dependent chromatin remodeling complex. It functions to regulate the structure of DNA (chromatin) to either allow or deny access of transcription factors to their respective promoters. The SWI/SNF complex contains about 10 components, raising the possibility that genetic alterations of members other than *SMARCB1* could be involved in AT/RT pathogenesis. Recently, inactivation of the ATPase subunit *SMARCA4* (also known as *BRG1*) was shown in the tumor cells of two sisters with rhabdoid tumors lacking the *SMARCB1* mutation.³³ Another case of a supratentorial AT/RT in a child was reported to have a homozygous *SMARCA4* mutation with retained *SMARCB1* staining.³⁴

8.1.2 Cerebrovascular Diseases

Cerebral Cavernous Malformation

Cerebral cavernous malformations (CMs), also known as cavernomas, cavernous angiomas, or cavernous hemangiomas, are congenital vascular hamartomas that consist of thin-walled vascular channels without intervening normal brain parenchyma. Although cerebral CMs can occur sporadically, some may arise in an autosomal-dominant inherited form (► Fig. 8.4). Genetic linkage analyses in cerebral CMs have mapped and identified cerebral CM genes at three different loci: *CCM1* on human chromosome 7q21.2, *CCM2* on 7p15-p13, and *CCM3* on 3q25.2-q27.³⁵ These cerebral CM genes encode proteins called K-Rev interaction trapped 1 (Krit1), *MGC4607*, and Programmed Cell Death 10 (PDCD), respectively. The cerebral CM proteins interact with each other and regulate endothelial cell-to-cell adhesion, cell shape remodeling, and cell adhesion to the extracellular matrix, as reviewed recently.³⁶ To date, a number of germline mutations on these genes have been reported, and almost all mutations lead to a premature termination codon, resulting in a loss of protein function. Although the precise mechanism of inherited cerebral CM pathogenesis has not yet been clarified, a two-hit mechanism is implicated in cerebral CM formation,³⁷ as was suggested by Knudson⁵⁸ in retinoblastoma formation (► Fig. 8.5). According to this two-hit model, cerebral CM formation requires a complete loss of any of the three cerebral CM proteins within endothelial cells lining capillary cavities, which results from a germline mutation in one of the two alleles (first hit) and a somatic mutation in the other allele

These lesions represent cavernous malformations, and the presence of multiple lesions suggests the diagnosis of familial cerebral cavernous malformation.

(second hit). In fact, biallelic germline and somatic mutations in each of the three cerebral CM genes have recently been reported, strongly supporting the two-hit mechanism of cerebral CM formation.^{38–40}

Moyamoya Disease

Moyamoya disease is a progressive cerebral angiopathy characterized by bilateral stenosis or occlusion of the terminal portion of the internal carotid arteries and/or proximal portions of the anterior and the middle cerebral arteries, accompanied by an aberrant collateral vascular network called moyamoya vessels (► Fig. 8.6). Moyamoya disease is known to be most prevalent in East Asian countries, such as Japan, Korea, and China,⁴¹ and has a higher prevalence in females, with a female-to-male ratio ranging from 1.8:1 to 2.18:1.^{41,42} Given the fact that in Japan approximately 12 to 15% of moyamoya diseases are familial forms,⁴¹ genetic factors have been implicated in the pathogenesis of moyamoya disease. Previous linkage analyses have revealed several gene loci at 3p24.2-p26, 6q25, 8q23, and 17q25.3 linked to moyamoya disease⁴³; however, relevant genes predisposing to this disease have remained largely unknown until recently. One of the most promising discoveries in this disease was shown in a recent genome-wide association study, which first identified a susceptibility gene for moyamoya disease called *RNF213* at the 17q25.3 locus.² A more extensive study characterized the biological role of the RNF213 protein in

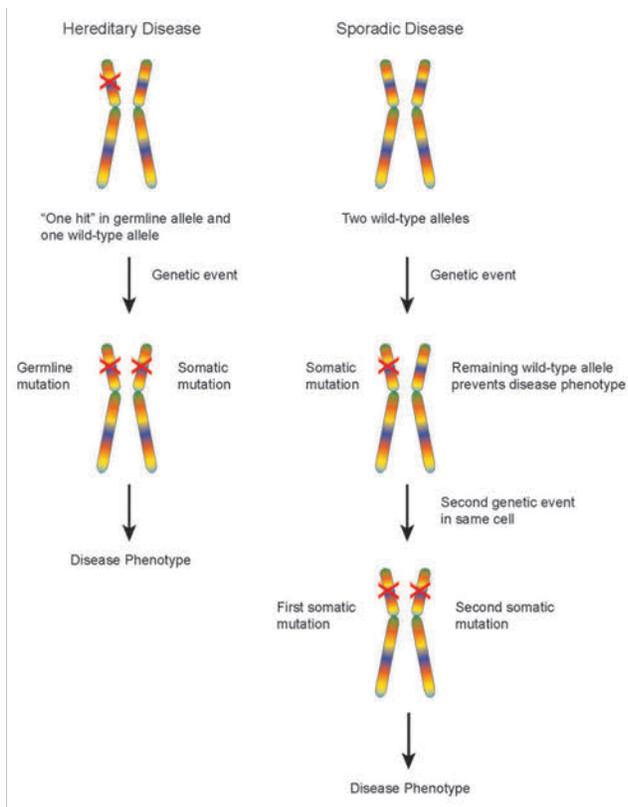

Fig. 8.5 Knudsonian two-hit mechanism was originally described in families in which multiple individuals were affected with retinoblastoma. Children in these families developed tumor(s) at a younger age and were more likely to develop multiple tumors. Knudson suggested that these children were born with one “hit” in the germline, so only one additional somatic event was required for tumorigenesis to occur. Children with sporadic tumors were born with no hits in the germline, and therefore two hits were required in any given cell for a tumor to be initiated. This would account for the lower incidence of tumors in the general population, the later age at onset, and absence of multiple tumors. This two-hit mechanism theory has been implicated in other neurosurgical diseases, such as familial cerebral cavernous malformation.

angiogenesis in zebrafish.⁴³ A further genetic study of *RNF213* in Japanese patients with moyamoya disease has demonstrated an *RNF213* sequence variant, c.14575G > A, resulting in an arginine to lysine substitution, in 39 of 41 familial cases of moyamoya disease (95.1%), in 129 of 163 sporadic cases (79.2%), and in 5 of 283 normal control individuals (1.8%). Interestingly, a homozygous c.14576G > A variant significantly correlated with earlier onset of the disease and known poor prognostic factors, such as infarctions at initial manifestation and involvement of the posterior cerebral arteries, suggesting that it may be used as a predictive factor for severe moyamoya disease.⁴⁴ Future studies will undoubtedly clarify the role of the *RNF213* gene in moyamoya disease.

8.1.3 Congenital and Developmental Disorders

Craniosynostosis

Craniosynostosis, characterized by premature fusion of one or more skull sutures, is one of the most common craniofacial anomalies, with an estimated incidence of approximately 1 in 2,500 live births.⁴⁵ Since a specific missense mutation in the *MSX2* gene was first described in association with craniosynostosis in 1993, several causative genes have been identified associated with the pathogenesis of craniosynostosis. To date, mutations in the *TWIST1*, *EFNB1*, *POR*, and *RAB23* genes and in three of the four fibroblast growth factor receptor (FGFR) family of genes, *FGFR1*, *FGFR2*, and *FGFR3*, have been shown to be involved with several types of craniosynostosis (► Table 8.1). A recent genetic and cytogenetic study in a large cohort of patients with craniosynostosis has found genetic causes of craniosynostosis in 21% of the cases, consisting of chromosome abnormalities in 14% and single-gene mutations in 86%. Among those cases with genetic alterations in this series, mutations were seen most frequently in *FGFR2* (32%), followed by *FGFR3* (25%), *TWIST1* (19%), and *EFNB1* (7%).⁴⁶

The *FGFR* genes encode transmembrane tyrosine kinase receptors, which consist of an extracellular ligand-binding domain with three immunoglobulin-like loops (IgI, IgII, and IgIII),

a transmembrane domain (TM), and two split intracellular tyrosine kinase domains (TK1 and TK2). Binding of its ligand, fibroblast growth factor, to FGFRs induces FGFR dimerization and autophosphorylation, subsequently leading to phosphorylation of downstream signaling elements. Mutations in *FGFR2*, the most common genetic event in craniosynostosis, are largely localized, but not limited, to the linker region between IgII and IgIII or in the IgIII loop encoded by exon IIIa or IIIc,^{47,48} and these mutations result in constitutive activation of the receptor or increased affinity for ligand. In contrast, most mutations seen in *TWIST1*, which encodes a transcription factor with a basic helix–loop–helix domain, are likely to produce premature termination of the protein, resulting in a loss of protein function. Further details underlying the molecular mechanisms of craniosynostosis are well described in the literature.⁴⁸

Holoprosencephaly

Holoprosencephaly is the most common developmental defect of the forebrain and midface and results from incomplete midline cleavage of the prosencephalon. Neurosurgeons are frequently involved in these cases when hydrocephalus develops and requires cerebrospinal fluid diversion. Holoprosencephaly is genetically and phenotypically heterogeneous, and the “multiple-hit” hypothesis is now a widely accepted model for this disease.⁴⁹ According to this model, combinations of mutations in different genes lead to holoprosencephaly with various degrees of severity.⁵⁰ Point mutations or deletions in four major genes are the leading cause of holoprosencephaly susceptibility: *SHH* (7q36), *ZIC2* (13q32), *SIX3* (2p21), and *TGIF* (18p11.3).⁵¹ Additional genes with a less important role in the occurrence of holoprosencephaly have also been identified: *GLI2* (2q14), *PTCH1* (9q22.3), *DISP1* (1q42), *NODAL* (10q22.1), and *FOXH1* (8q24.3). These minor genes are infrequently mutated or deleted, and the dysfunction of only one of them appears insufficient to cause severe disease phenotypes.⁵¹

Recently, a large study including 645 probands and their relatives found mutations in the four main genes in 25% of cases.⁴⁹ Mutations in the *SHH*, *SIX3*, and *TGIF* genes were inherited in more than 70% of cases, while 70% of *ZIC2* mutations occurred de novo. The authors also showed a positive correlation between the severity of the holoprosencephaly phenotype and mutations in the *SHH*, *SIX3*, and *TGIF* genes, but no correlation was found with *ZIC2* mutations. Fifteen cases of double mutation were reported, which supports the hypothesis of holoprosencephaly as a multiple-hit process.⁴⁹

Lissencephaly

Lissencephaly is a neuronal migration disorder characterized by a lack of the normal cortical convolutions that produce cortical thickening and a smooth cerebral surface.

There are two pathologic subtypes: classic or type 1 lissencephaly and cobblestone or type 2 lissencephaly.

To date, type 1 lissencephaly has been associated with mutations of six genes, *LIS1*, *DCX*, *TUBA1A*, *ARX*, *RELN*, and *VLDLR*.⁵² Mutations in these genes are associated with different disease phenotypes that include isolated lissencephaly (without any associated malformation outside the brain), Miller–Dieker syndrome, subcortical band heterotopia, X-linked lissencephaly with abnormal genitalia, and lissencephaly with cerebellar hypoplasia (► Table 8.2). The *LIS1* gene on chromosome 17p13.3 controls mitotic spindle orientation, and its deletion causes dysfunction of dynein, a microtubular protein involved in neuronal migration. Complete deletion of both *LIS1* and the *YHAWAE* gene on chromosome 17p13 causes the Miller–Dieker syndrome, a severe form of type 1 lissencephaly associated with facial dysmorphisms. The *DCX* gene on chromosome Xq22.3 encodes a microtubule-associated protein, and its mutation causes classic lissencephaly in males and a migration disorder called subcortical band heterotopia in females.⁵³ Recently, *TUBA1A* (alpha tubulin complex) mutations on chromosome 12q12–q14 were also described in classic lissencephaly. This gene encodes alpha tubulin protein, a major component in microtubule assembly that is essential for neuronal migration. The *ARX* gene, located at Xp22.1, encodes a transcription factor expressed in interneurons of the forebrain and in the male gonad. *ARX* mutations cause X-linked lissencephaly with anomalous genitalia in affected hemizygous male children. The *RELN* gene on chromosome 7q22.1 encodes an extracellular matrix-associated protein (reelin) that plays a critical role in regulating neuronal migration during cortical development. This protein interacts with the very low-density lipoprotein receptor (*VLDLR*), activating downstream signaling that influences cell migration. Patients with mutations in these genes have lissencephaly associated with cerebellar hypoplasia and the absence of foliation.⁵⁴ Several genes have been implicated in the etiology of type 2 lissencephaly, and three syndromes were described: Walker–Warburg syndrome, Fukuyama congenital muscular dystrophy, and muscle–eye–brain disease (see ► Table 8.2). All these genes are involved in the glycosylation of components of extracellular matrix. When mutations occur, the integrity of the superficial cortical layer is compromised, and neurons overmigrate into the pial surface, giving origin to the typical cobblestone appearance.⁵²

Congenital Hydrocephalus

Congenital hydrocephalus is a critical neurosurgical disorder that comprises diverse conditions. These include primary hydrocephalus and secondary forms of hydrocephalus caused by antecedent events like intrauterine infections, trauma, intracranial hemorrhages, and tumors. Congenital hydrocephalus can also occur in association with neural tube defect or other CNS malformations (► Fig. 8.7).⁵⁵ Primary congenital hydrocephalus is not a rare disease, with an estimated incidence of approximately 0.2 to 0.8 per 1,000 live births.⁵⁶ However, genetic causes of this condition are not yet fully understood. A recent retrospective survey of a total of 75 patients with primary congenital hydrocephalus found cytogenetic or genetic abnormalities, such as trisomy 9 and L1 syndrome, in 14 of the 75 cases, but the cause of hydrocephalus was not detected in the rest of the cases.⁵⁵

L1 syndrome, an X-linked recessive disorder, is known to be the most common genetic cause of congenital hydrocephalus so far,⁵⁵ accounting for approximately 5% of cases of congenital hydrocephalus in males. It is characterized by hydrocephalus, agenesis or hypoplasia of the corpus callosum and corticospinal tracts, lower limb spasticity, mental retardation, and adducted thumbs, and it comprises several overlapping clinical phenotypes: X-linked hydrocephalus; MASA syndrome (*mental*

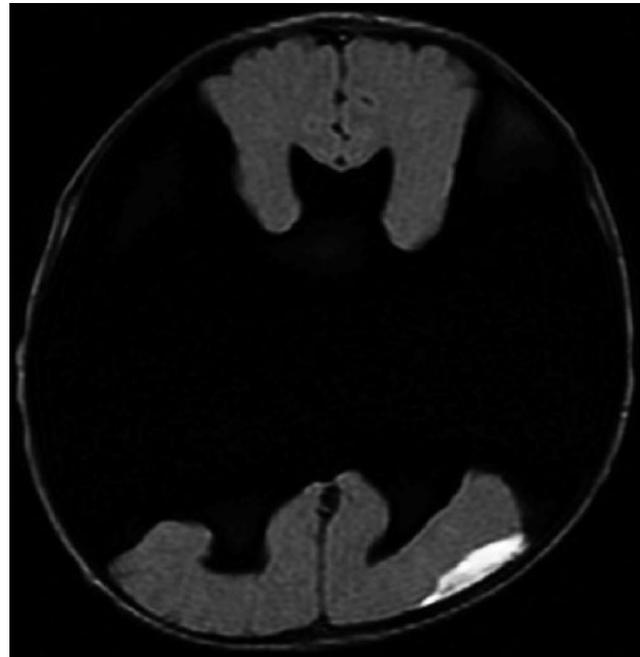

Fig. 8.7 Axial T1-weighted magnetic resonance image of a newborn with hydrocephalus caused by bilateral, severe schizencephaly. retardation, aphasia, shuffling, and adducted thumbs); X-linked hereditary spastic paraplegia type 1; and X-linked agenesis of the corpus callosum (► Fig. 8.8). The *L1CAM* gene at Xq28, which encodes L1 protein (neural cell adhesion molecule), is responsible for L1 syndrome. Since the first report of aberration in the *L1CAM* gene in an affected family with X-linked hydrocephalus, a number of *L1CAM* mutations have been described in association with L1 syndrome.⁵⁷ Furthermore, previous studies have provided close correlations between severity of L1 syndrome and mutation types in L1 protein.⁵⁷ For example, mutations leading to extracellular L1 protein truncation or absence tended to produce more severe clinical manifestations than mutations in the cytoplasmic L1 protein domain. Thus, *L1CAM* mutation analysis in L1 syndrome is becoming a clinically useful tool, not only for precise genetic counseling and prenatal diagnosis within affected families but also for prognosis.

8.2 Conclusion

The revolution in molecular genomics has allowed a better characterization of the genetic origins of pediatric neurosurgical diseases. The identification of molecular and clinical subtypes, along with the selection of reliable and validated biomarkers, adds another layer of relevance in patient care and opens avenues for future targeted therapies. Next-generation sequencing will also provide an enormous amount of data on the dysregulated signaling pathways and driver mutations, which will allow a better understanding of pathogenesis and the subsequent development of accurate preclinical models. The major challenge is to make these techniques a simple,

available, and reproducible tool in clinical practice. The obvious impact will be more effective prognosis, a better assessment of response to therapy, and the discovery of novel therapies.

Pearls

- A tandem duplication of the *BRAF* locus occurs in pilocytic astrocytoma.
- Molecular subclassification of medulloblastomas and ependymomas will allow the stratification of patients into appropriate risk groups and the tailoring of treatments according to the tumor genome.
- The first susceptibility gene for moyamoya disease, *RNF213*, has been identified.

9 Hydrocephalus

Amal Abou-Hamden and James M. Drake

The surgical management of hydrocephalus has undergone fantastic changes over the last generation of neurosurgeons: dramatic improvements in imaging with computed tomography (CT) and magnetic resonance (MR) imaging, remarkable innovative advances in cerebrospinal fluid (CSF) valve technology, bewildering complex computer models, and dramatic advances in endoscopic equipment and techniques. In terms of overall patient outcomes, one could conclude, however, that things are a little better, but “not much.” This frustrating yet fascinating dichotomy between technological advances and clinical outcomes makes hydrocephalus, first described by the ancients, one of the most understated and complex disorders. For pediatric neurosurgeons, it is the disorder that they most commonly treat. The challenge to the current generation of pediatric neurosurgeons is to solve this vexing problem, through a better understanding of basic science, better computer models, further technological advances, and most importantly a broad-based, concerted multi-disciplinary attack on this disorder. This chapter focuses on an overview of pediatric hydrocephalus. Further chapters will address its management with CSF shunts and endoscopy.

9.1 Definition

Hydrocephalus is possibly most simply defined as an increase in the fluid-containing spaces of the brain at increased pressure, resulting from an imbalance between CSF production and absorption or flow. This definition excludes other abnormalities of CSF dynamics, such as benign intracranial hypertension, in which the ventricles are not enlarged, and hydrocephalus ex vacuo, in which cerebral atrophy and focal destructive lesions lead to an abnormal increase of CSF passively. However, not all cases fall clearly within these definitions; patients with parenchymal destruction may develop progressive hydrocephalus, and patients with slit-ventricle syndrome may have a presentation akin to that of benign intracranial hypertension.

9.2 Classification

There is no universally accepted classification system for hydrocephalus. A number have been suggested,¹⁻⁵ which include the following:

- Communicating versus noncommunicating
- Obstructive versus absorptive
- Acquired versus congenital
- Genetic or central nervous system (CNS) malformation-associated versus isolated
- Intraventricular-obstructive versus extraventricular
- Simple versus complicated

The terms *communicating* and *noncommunicating* date back to the early 1900s and are based on the experimental studies of Dandy and Blackfan,⁶ who investigated the pathophysiology of hydrocephalus in which the aqueduct is obstructed. *Communicating* implies that the CSF has free flow into the subarachnoid

space, but in the absence of overproduction, it is generally accepted that CSF absorption is impaired (or obstructed) downstream at some point. The terms *compensated hydrocephalus* and “*arrested*” *hydrocephalus* are also older and generally refer to whether an increase in ventricular size is associated with evidence of raised intracranial pressure (ICP). In some cases, the gradual increase in ventricular size stabilizes by reaching a new equilibrium, and the patient has no symptoms or signs of raised ICP. In others, a patient is discovered incidentally to have large ventricles unassociated with any identifiable problems. However, patients with apparently arrested hydrocephalus may still develop symptoms and signs at a later date, so the process is not entirely static.⁷ Congenital hydrocephalus is present at birth and often is associated with developmental defects; acquired hydrocephalus occurs after development of the brain and ventricles.^{4,8} Hydrocephalus has also been classified based on the stage of development at the time that the ventricles became dilated.⁹ The various subtypes of fetal hydrocephalus are classified according to the mechanism of obstruction to the flow of CSF; they include primary or simple hydrocephalus, with a single point of obstruction to flow; dysgenetic hydrocephalus, with complex abnormalities of the CNS, such as Arnold-Chiari malformation; and secondary hydrocephalus resulting from tumor or bleeding. This classification is cross-referenced to the stage of fetal development (i.e., neuronal maturation, cell migration). This classification may prove useful in deciding when treatment may be futile if the legal period for terminating a pregnancy has elapsed and in identifying potential candidates for early delivery or fetal surgery.⁵

Extraventricular obstructive hydrocephalus is now recognized to represent, almost universally, benign pericerebral collections of infancy that are usually familial, resolve with time, and almost never require treatment.¹⁰ Exceptions include genetic conditions, such as certain mucopolysaccharidoses, achondroplasia, Sotos syndrome, and glutaric aciduria type 1, which are often associated with developmental delay. In these cases, identification is important, as therapeutic options exist for many forms of mucopolysaccharidosis and for glutaric aciduria type 1.¹¹

9.3 Epidemiology

The exact incidence of hydrocephalus is hard to ascertain as it is generally secondary to some other insult, including tumor, infection, trauma, or prematurity. Cited rates in newborns range from 0.3 to 4 per 1,000 live births. When it occurs as a single congenital disorder, the incidence of hydrocephalus has been reported as 0.9 to 1.5 per 1,000 births.¹²⁻¹⁶ One estimate suggested that approximately 125,000 persons are living with CSF shunts and that 33,000 shunts are placed annually in the United States.¹⁷

The incidence of pediatric hydrocephalus has declined in many developed countries.¹⁰ Antenatal screening, genetic testing, and pregnancy termination have reduced the incidence of the congenital malformations of the brain that cause

hydrocephalus. The incidence of open neural tube defects has also decreased precipitously as a result of maternal folate supplementation, antenatal screening, and termination of pregnancy based on superior antenatal imaging with ultrasound and MR imaging. The incidence of CSF shunting in open neural tube defects, formerly reported to be as high as 90%, has also declined, possibly as a result of a generally more conservative approach, and the selection of anatomically lower lesions for delivery with a lower requirement for shunting.^{18,19} The incidence of intraventricular hemorrhage (IVH) has decreased as a result of better perinatal management of prematurity.²⁰

9.4 Cerebrospinal Fluid Production, Circulation, and Absorption

CSF is produced by two mechanisms. Most of the CSF (50 to 80%) is thought to be secreted by the choroid plexus within the cerebral ventricles. Extrachoroidal CSF production in subarachnoid sites and by way of a transependymal route has also been documented. About 20% or more of the CSF is derived from brain extracellular fluid created as a by-product of cerebral metabolism.^{21–23} Normally, rates of production (0.35 mL/min or approximately 400 to 500 mL/d) and absorption of CSF are equal. Total CSF volume is 65 to 140 mL in children and 90 to 150 mL in adults

The process of CSF formation by the choroid plexus includes plasma ultrafiltration and secretion. Secretion, an energy-dependent process, is initiated by hydrostatic pressure in the choroidal capillaries and by active transport of sodium. The enzymes sodium-potassium adenosine triphosphatase and carbonic anhydrase partly regulate CSF secretion.²³ CSF production has been reported to remain constant across the normal range of ICP,²⁴ with CSF production decreasing when the ICP approaches mean arterial pressure. There have been reports, however, of downregulation of CSF production in patients with chronic hydrocephalus.²⁵ In contrast to CSF production, CSF reabsorption is not an energy-dependent process.²² Information gained from MR imaging analysis of CSF movement demonstrates pulsatile to-and-fro motion of CSF within the lateral ventricles, produced from a brain-pumping motion that ejects the CSF and causes a net downward flow.²⁶

Historically, it has been held that CSF is absorbed into the vascular system mainly through the arachnoid villi within the arachnoid granulations covering the brain and spinal cord leptomeninges.^{27,28} This process is thought to be passive and not energy-dependent. A layer of endothelium within the arachnoid villi separates the subarachnoid CSF space from the vascular system. Water and electrolytes pass freely across these arachnoid membranes. There is normally a 5- to 7-mm Hg difference in pressure between the dural venous sinuses and the subarachnoid space. This is presumed to be the hydrostatic force behind the absorption of CSF. Larger proteins and macromolecules cannot pass through intercellular junctions but are selectively transported across the cytoplasm of endothelial cells by an active process involving micropinocytosis.²⁸ Increased absorption through the arachnoid villi protects the brain from transient increases in ICP.²⁹ This concept has, however, been

recently challenged. Newborn infants do not have visible arachnoid granulations yet maintain normal CSF circulation. Johnston et al^{30–32} have produced evidence in a number of animal species and human cadavers that the main route of CSF absorption is via the olfactory nerves, cribriform plate, and nasal lymphatics. At pressures above normal, the arachnoid granulations become active, perhaps explaining earlier experimental findings. Absorption of CSF across brain tissue into capillaries has also been proposed,³³ and according to this theory, the distending force in the production of chronic hydrocephalus is an increased systolic pulse pressure in the brain tissue that is due to decreased intracranial compliance.

9.5 Etiology and Pathophysiology

Hydrocephalus can be a symptom of a large number of disorders: it is associated with tumors and infections and occurs as a complication of prematurity and trauma.^{34–36} It is also seen in apparent isolation. High-resolution MR imaging of postnatal life has provided clues to the etiologies of hydrocephalus, which in the past would have been labeled as idiopathic; some of these include IVH (► Fig. 9.1 A–C), aqueduct stenosis (► Fig. 9.2), and migrational abnormalities.¹⁰ The etiologies of hydrocephalus in one series of pediatric patients are shown in ► Table 9.1.

Hydrocephalus is due to abnormal CSF reabsorption, flow, or rarely overproduction.

The main situation in which CSF production is increased enough to cause hydrocephalus is the presence of a choroid plexus papilloma. These tumors contain functional choroid epithelium and can produce very large amounts of CSF. However, even in such cases, reabsorption is probably defective because otherwise-normal individuals can usually tolerate the elevated CSF production rate of these tumors. CSF accumulation, in turn, leads to raised ICP.

The etiology of hydrocephalus depends upon the age of the child. During the neonatal period to late infancy (0 to 2 years), hydrocephalus is usually caused by perinatal hemorrhage, meningitis, or developmental abnormalities, the most common being aqueduct stenosis. The hydrocephalus seen in babies with spina bifida usually results from an associated Chiari malformation.

In early to late childhood (2 to 10 years), the most common causes of hydrocephalus are posterior fossa tumors and aqueduct stenosis.

9.5.1 Congenital Causes in Infants and Children

Approximately 55% of all cases of hydrocephalus are congenital. Primary aqueductal stenosis accounts for approximately 5% of cases of congenital hydrocephalus, whereas aqueductal stenosis secondary to neoplasm, infection, or hemorrhage accounts for another 5%.³⁴ Primary aqueduct stenosis usually presents in infancy. Its morphology may be that of “forking” of the aqueduct, an aqueductal septum, “true” narrowing of the aqueduct, or X-linked aqueduct stenosis. Bickers-Adams syndrome is an X-linked form of hydrocephalus accounting for 7% of cases in males. It is characterized by stenosis of the

aqueduct of Sylvius, severe mental retardation, and in 50% of cases by an adduction–flexion deformity of the thumb. Secondary aqueduct stenosis is due to gliosis secondary to intrauterine infection or germinal matrix hemorrhage.³⁷

Anatomical malformations frequently observed with idiopathic congenital hydrocephalus include Chiari malformations, Dandy-Walker malformation, and others.^{36,38} Dandy-Walker malformation is associated with atresia of the foramina of Luschka and Magendie and affects 2 to 4% of newborns with hydrocephalus. About 50% of all patients with Dandy-Walker malformation develop hydrocephalus. The dilated fourth ventricle does not communicate effectively with the subarachnoid space. In Chiari malformations, hydrocephalus may occur with fourth

ventricle outlet obstruction in Chiari type 1 malformation and is commonly associated with myelomeningocele in Chiari type 2 malformation.

Hydrocephalus occurs in approximately 80 to 90% of patients with myelomeningocele; of these cases, 50% are obvious at birth.^{18,39}

Neonatal hydrocephalus can also be part of a major cerebral malformation, such as an encephalocele or holoprosencephaly, or can be associated with inherited metabolic diseases, such as achondroplasia and Hurler disease. Other causes of congenital hydrocephalus include agenesis of the foramen of Monro, congenital tumors, arachnoid cysts and vascular malformations, and intrauterine toxoplasmosis.

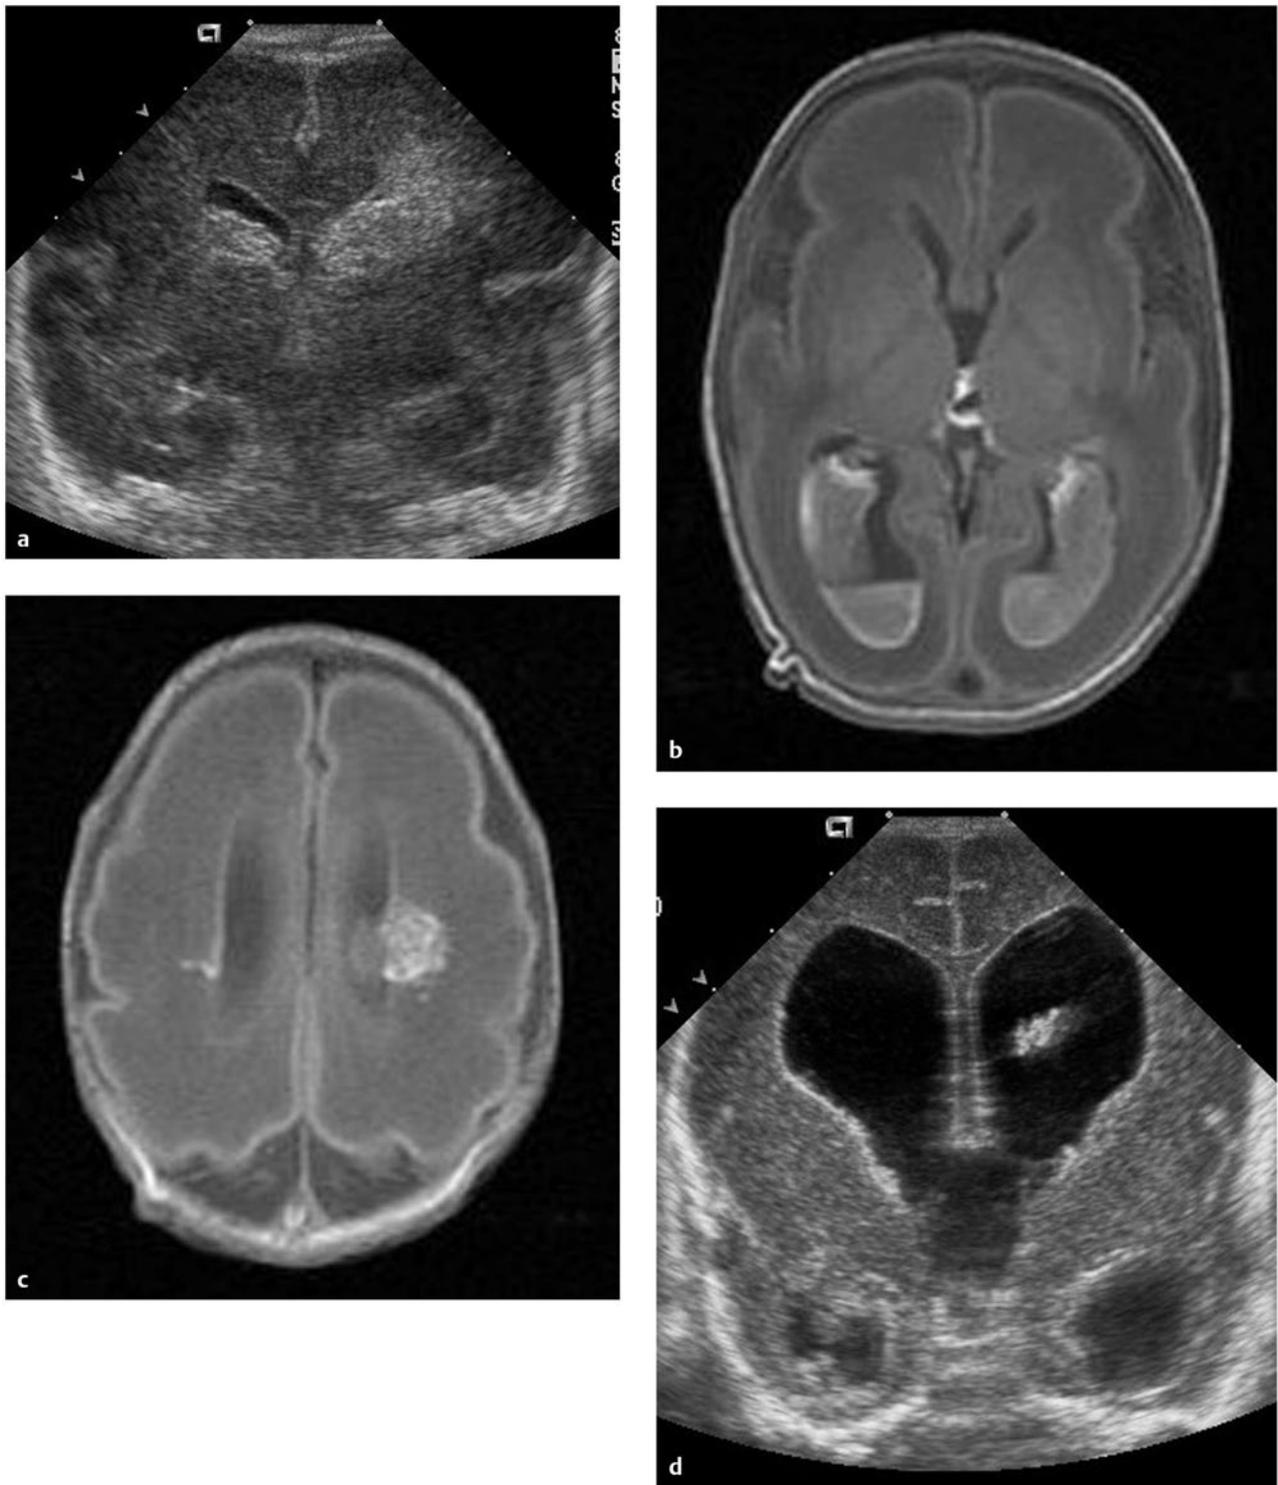

Fig. 9.2 Intrauterine magnetic resonance image of severe hydrocephalus. (a-d) Sequential coronal views.

9.5.2 Acquired Causes in Infants and Children

Infective causes of hydrocephalus include meningitis, especially bacterial, which can lead to hydrocephalus by either inflammatory aqueduct stenosis or leptomeningeal fibrosis. In some

geographic areas, parasitic disease, such as intraventricular cysticercosis, can cause hydrocephalus by mechanical obstruction.

Post-hemorrhagic hydrocephalus occurs following IVH, which can be related to prematurity, head injury, or rupture of a vascular malformation. Communicating hydrocephalus after subarachnoid hemorrhage is more common in adults and is

rarely seen in children. Over the past two decades, there has been remarkable improvement in the survival of extremely low-birth-weight infants; however, the most immature of these infants remain at increased risk for neonatal complications that potentially affect long-term neurologic developmental outcome, including IVH. The risk for severe IVH varies inversely with gestational age, with an overall incidence of 7 to 23%.^{40–42} Approximately one-third of extremely low-birth-weight infants with an IVH develop post-hemorrhagic hydrocephalus, and 15% of them will require shunt insertion.^{43–45}

Hydrocephalus after IVH is usually ascribed to fibrosing arachnoiditis, meningeal fibrosis, and subependymal gliosis, which impair the flow and reabsorption of CSF. Recent experimental studies have suggested that acute parenchymal compression and ischemic damage and increased parenchymal and perivascular deposition of extracellular matrix proteins—probably due at least partly to upregulation of transforming growth factor- β (TGF- β)—are further important contributors to the development of the hydrocephalus. IVH is associated with damage to periventricular white matter,

and the damage is exacerbated by the development of hydrocephalus; combinations of pressure, distortion, ischemia, inflammation, and free radical-mediated injury are probably responsible.⁴⁶

Mass lesions account for 20% of all cases of hydrocephalus in children. These are usually tumors such as medulloblastoma, astrocytoma, and ependymoma, but cysts, abscesses, vascular malformations, or hematomas also can be the cause. Twenty percent of pediatric patients develop hydrocephalus requiring shunting following posterior fossa tumor removal. This may be delayed up to a year. Risk factors for the requirement of CSF diversion in this group include age younger than 2 years, papilledema, enlarged ventricles, presence of metastases, and tumor type.⁴⁷ Increased venous sinus pressure can also lead to hydrocephalus. This can be related to achondroplasia, some forms of craniosynostosis, or venous sinus thrombosis.

Iatrogenic causes of hydrocephalus include hypervitaminosis A, which can lead to hydrocephalus by increasing secretion of CSF or by increasing permeability of the blood-brain barrier. Hypervitaminosis A is a more common cause of idiopathic intracranial hypertension.^{48,49}

9.6 Clinical Characteristics

The clinical features of hydrocephalus depend on the age of the patient at presentation and the time of onset in relation to closure of the cranial sutures. With the current advances in antenatal monitoring, the majority of congenital cases of hydrocephalus are diagnosed early (► Fig. 9.3), allowing planned cesarian delivery in the moderate to severe cases in which cephalopelvic disproportion is expected.

9.6.1 Symptoms and Signs in Infants

Hydrocephalus can present as acute raised ICP, but because of the relative distensibility of the infant skull, the presentation may be more subtle, with failure to thrive and achieve

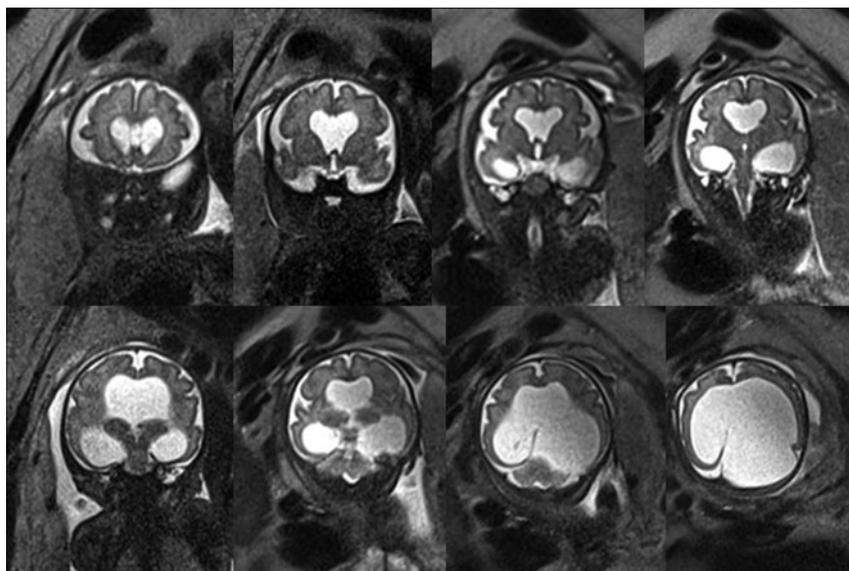

Fig. 9.3 Obstructive hydrocephalus from (a) aqueduct occlusion, (b) tectal glioma, and (c) suprasellar arachnoid cyst.

milestones. Infants with hydrocephalus may be drowsy and irritable. Poor feeding and vomiting are common. These infants may have apneic spells, bradycardia, and a bulging, tense anterior fontanel. Head circumference increases abnormally across centiles: the head circumference is at or above the 98th percentile for age. The scalp veins may be distended, the scalp skin thin and shiny, and the cranial sutures splayed. In the minority of cases, an abnormally large head is present at birth. In most, however, the hydrocephalus only gradually becomes obvious. In advanced cases, clinical examination reveals a significant craniofacial disproportion with expansion of the dome and low-set ears and eyes. In very severe cases, in which the cerebral cortex is thinned, transillumination of the cranial cavity may be possible. Epileptic seizures are rarely seen as a result of hydrocephalus alone.

Papilledema is rare in this age group, although funduscopy may reveal retinal venous engorgement. Oculomotor abnormalities may include abducens nerve palsy. Upgaze palsy from third ventricular pressure on the midbrain tectum, producing a “setting-sun” sign, can be observed, although this is usually absent in premature infants. In babies over the age of 6 months, limb tone may be increased, with spasticity preferentially affecting the lower limbs. However, some infants with definite hydrocephalus exhibit no such signs, as hydrocephalus may have developed slowly and the splaying of the sutures may have prevented the ICP from rising considerably. In fact, some infants with hydrocephalus after intraventricular hemorrhage may show hypotonia.

9.6.2 Symptoms and Signs in Older Children

In older children (older than 2 years), the head circumference is usually within normal limits if hydrocephalus develops after closure of the cranial sutures or may be increased in children with preexisting (infantile) but unrecognized progressive hydrocephalus.

Learning problems and reduced intellectual function are common, and neurologic development may be delayed. School-age children may have deteriorating school performance as a result of headaches, failing mental function, memory loss, or behavioral disturbances. More acutely, these children present with symptoms and signs of increased ICP, such as headache, nausea and vomiting, drowsiness, gait changes, papilledema, and upgaze and/or abducens palsy. Failure of upward gaze is due to pressure on the tectal plate through the suprapineal recess. The limitation of upward gaze is of supranuclear origin. When the pressure is severe, other elements of the dorsal midbrain syndrome (Parinaud syndrome) may be observed, such as light–near dissociation, convergence–retraction nystagmus, and eyelid retraction (Collier sign).

Evidence of abnormal hypothalamic function (e.g., short stature or gigantism, obesity, delayed puberty, primary amenorrhea or menstrual irregularity, and diabetes insipidus) may occur secondary to increased ICP or dilatation of the third ventricle. Difficulty in walking may occur secondary to truncal and limb ataxia or limb spasticity. This affects the lower limbs preferentially because the periventricular pyramidal tract is stretched by the enlarged ventricles.

Neck pain may indicate associated tonsillar herniation, and blurred vision may be present as a consequence of papilledema, which if left untreated leads to optic atrophy.

9.7 Genetics

Although commonly considered a single disorder, human hydrocephalus is a collection of heterogeneous, complex, and multifactorial disorders. A growing body of evidence suggests that genetic factors play a major role in the pathogenesis of hydrocephalus.⁵⁰ Congenital hydrocephalus may occur alone (nonsyndromic) or with other anomalies (syndromic). It is estimated that about 40% of cases of hydrocephalus have a possible genetic etiology.⁵¹

In genetic terms, the isolated (nonsyndromic) form of hydrocephalus is a primary and major phenotype caused by a specific faulty gene. In syndromic forms of congenital hydrocephalus, it is difficult to define the defective gene because of the association with other anomalies. Autosomal-recessive, autosomal-dominant, X-linked recessive,⁵² and X-linked dominant⁵³ forms of hydrocephalus are recognized.

At least 43 mutants/loci linked to hereditary hydrocephalus have been identified in animal models and humans. To date, nine genes associated with hydrocephalus have been identified in animal models, whereas only one such gene has been identified in humans: the hydrocephalus (X-linked) gene.⁵¹ Cases of X-linked hydrocephalus (HSAS1, OMIM) comprise approximately 5 to 15% of the congenital cases with a genetic cause.^{51,54}

The gene responsible for X-linked human congenital hydrocephalus is at Xq28 and encodes L1CAM (L1 cell adhesion molecule).⁵⁵ CRASH (corpus callosum agenesis, retardation, adducted thumbs, shuffling gait, and hydrocephalus) incorporates the L1 mutations that were formerly regarded as multiple separate entities.⁵⁶ Congenital aqueductal stenosis can also be caused by autosomal-recessive mechanisms (OMIM 236635).⁵⁷ In general, the recurrence risk for congenital hydrocephalus, excluding X-linked hydrocephalus, is low. Empiric risk rates range from less than 1% to 4%,⁵⁸ indicating the rarity of autosomal-recessive congenital hydrocephalus.^{51,54,59} However, multiple human kindreds with congenital hydrocephalus have been reported.^{50,51,54,60}

Hydrocephalus has been observed in many mammals.⁵⁰ Review of the molecular etiologies shows a very diverse set of pathogenetic mechanisms. Perturbation of almost any molecule that plays a crucial role in early brain development and the sequential regulation of CSF dynamics may be involved. Hydrocephalus may also be caused by a malfunction of the ependymal cells,⁶¹ mesenchymal cells,^{62,63} growth factor signaling,^{64,65} disruption of extracellular matrix (ECM),^{66,67} and membrane fusion events (synaptosomal-associated protein, or SNAP).⁶⁸

9.8 Imaging Studies

9.8.1 Cranial Ultrasound

Ultrasound is by far the quickest, cheapest, and most convenient method for demonstrating ventricular enlargement in infants with an open fontanel, particularly premature infants

with post-hemorrhagic hydrocephalus, and for serial imaging in follow-up. It is also useful for the diagnosis of intrauterine hydrocephalus. Measurement of ventricular width from the midline to the lateral border of the lateral ventricle in the midcoronal view is the measurement with the least interobserver variability, and centiles for gestational age have been compiled.⁶⁹

No sedation is required for acquiring of ultrasound images, and the procedure can be repeated frequently without any adverse effects. It may not visualize the posterior fossa well and may not always establish an etiologic diagnosis.

9.8.2 Computed Tomography

CT demonstrates the size and morphology of the ventricles and periventricular lucency, and it can reveal underlying pathologies, such as hemorrhage and posterior fossa tumors. Baseline imaging of asymptomatic patients (especially after shunt revision) may serve as a reliable study for comparison with subsequent imaging when patients become symptomatic. CT is widely available in many facilities and often does not require sedation of the child. However, there is mounting concern about the effects of exposure to radiation, so that alternate imaging⁷⁰ultrasound or rapid-sequence MR imaging—is frequently preferred.⁷¹

9.8.3 Magnetic Resonance Imaging

MR imaging provides a better morphological definition and a better etiologic diagnosis, such as the presence of low-grade gliomas or colloid cysts, which may not be demonstrated on CT. It is better for evaluating Chiari malformations and cerebellar or periaqueductal tumors. Cine MR imaging is an MR imaging technique to measure CSF stroke volume in the cerebral aqueduct. This is used for demonstrating the patency of third ventriculostomy fenestration. The limitations of MR imaging are that children often require a general anesthetic and that programmable shunt valves require reprogramming after MR imaging. In patients with acute hydrocephalus characterized by ventricular enlargement and transependymal edema with loss of sulci, the diagnosis is usually very obvious. However, there may be no reliable measurement values that can confirm or exclude the presence of hydrocephalus in a single series of images in some patients. Serial imaging demonstrating an increase in ventricular size may be required in equivocal cases. Conversely, an apparently normal ventricular size cannot exclude active hydrocephalus in a patient with a preexisting shunt, for example. A number of methods have been used to attempt to define hydrocephalus quantitatively on CT or MR imaging studies.⁷² Hydrostatic hydrocephalus is suggested in either of the following situations:

1. Both temporal horns have a width of 2 mm or more and the sylvian and interhemispheric fissures are not visible.
2. Both temporal horns have a width of 2 mm or more and the ratio of the largest width of the frontal horns to the internal diameter from inner table to inner table at this level is greater than 0.5.

Other features suggestive of hydrostatic hydrocephalus include the following: ballooning of the frontal horns of the lateral

ventricles and third ventricle; periventricular hypoattenuation on CT or periventricular high-intensity signal on T2-weighted imaging and fluid-attenuated inversion recovery [FLAIR] sequences on MR imaging, suggesting transependymal exudate or migration of CSF; compression of the sulci and basal cisterns; upward bowing of the corpus callosum and downward displacement of the floor of the third ventricle on sagittal MR imaging. The Evans ratio is the ratio of largest width of the frontal horns to the maximal biparietal diameter. A ratio greater than 30 is suggestive of hydrostatic hydrocephalus. A modification of the Evans ratio, the frontal occipital horn ratio, may be more accurate and has been used in a number of prospective studies to quantify the degree of hydrocephalus and the response to treatment.^{73,74}

9.8.4 Radiologic Criteria for Chronic Hydrocephalus

Skull radiographs may depict erosion of the sella turcica, or a “beaten copper” cranium. The latter can also be seen in craniosynostosis. The temporal horns may be less prominent than in acute hydrocephalus, and the third ventricle may herniate into the sella turcica. The corpus callosum may be atrophic; this is best appreciated on sagittal MR imaging. In infants with chronic hydrocephalus, sutural diastasis and delayed closure of the fontanelles may be seen.

In communicating hydrocephalus, all ventricles are dilated. If the lateral and third ventricles are dilated and the fourth ventricle is small, it is likely that the obstruction is at the level of the aqueduct of Sylvius. MR imaging will help determine the cause, such as defining the presence of an obstructing tumor.

9.9 Diagnosis

Modern ultrasonography and, since the late 1980s, fetal MR imaging have significantly improved the ability to detect ventricular enlargement as a result of hydrocephalus in utero. Antenatal ultrasound and MR imaging provide reasonably detailed fetal brain anatomy, detect malformations, and can detect fetal ventriculomegaly as early as 17 to 21 weeks and 8 to 21 weeks, respectively.^{75,76} Normative data for ventricular size allow serial investigation during gestation.⁷⁷

Anatomical ventriculomegaly is not sufficient to diagnose hydrocephalus. When making a diagnosis of hydrocephalus in neonates or infants, it is essential to establish that there is a truly abnormal rate of skull growth. Recording head circumference and comparing it with body weight and length centile charts are an integral part of the postnatal follow-up of any child. The head circumference must be recorded and plotted on an accepted growth curve chart with the patient's exact age or, in premature infants, the gestational age. In the presence of hydrocephalus, any of the following may be observed: head circumference greater than 2 standard deviations above normal or out of proportion to body length or weight, upward deviations (crossing centile curves), or continued head growth of greater than 1.25 cm per week.

Evaluation of the patient with an enlarged head entails consideration of the many causes of macrocephaly, including hydrocephalus. Evaluation should include a history of trauma or

CNS infection. The family history may demonstrate X-linked hydrocephalus caused by stenosis of the aqueduct of Sylvius or may reveal familial macrocephaly.

After a full review of the pregnancy, delivery, and neonatal history, as well as the clinical examination and ultrasound examination, it is usually possible to classify the hydrocephalus into an etiologic group. If no obvious explanation for the hydrocephalus can be found, then intrauterine infection should be investigated. Coagulation factor deficiency as well as thrombocytopenia should be excluded; isoimmune thrombocytopenia and coagulation factor V deficiency can present as congenital hydrocephalus resulting from congenital IVH.

9.9.1 Differential Diagnosis

Besides hydrocephalus, causes of increasing head size include chronic subdural effusion or hematoma, pseudotumor cerebri, neurofibromatosis, metabolic abnormalities of bone or brain, and cerebral gigantism (Soto syndrome). There are also benign familial forms.

Benign extracranial hydrocephalus is a condition of infants and children in which enlarged subarachnoid spaces are accompanied by increasing head circumference with normal or mildly dilated ventricles. This condition is also known as benign subdural collections of infancy or pericerebral CSF collections. It has been postulated by some to be a variant of communicating hydrocephalus but tends to run a benign course and stabilize by 12 to 18 months of age.⁷⁸⁻⁸⁰ Close serial monitoring of the head circumference and follow-up imaging with CT or MR imaging is recommended to monitor for ventriculomegaly. Shunting is rarely, if ever, required. A rare but striking condition that can mimic hydrocephalus is hydranencephaly, a post-neurulation defect that results in total or nearly total absence of the cerebral tissue; the intracranial cavity is filled with CSF. This is usually due to bilateral internal carotid artery infarcts or infection.⁸¹ Other brain malformations, such as agenesis of the corpus callosum and alobar holoprosencephaly, may also be associated with hydrocephalus but more often represent expansion of the third ventricle and separation of the lateral ventricles. Hydrocephalus ex vacuo is due to atrophy rather than altered CSF dynamics. Certain metabolic and degenerative disorders, such as glycogen storage and Alexander disease, can cause macrocephaly. Brain tumors of infancy may reach an enormous size, producing a large head apart from whether there is associated hydrocephalus. Finally, there may be a family history of large heads.

9.10 Pathology

The precise pathologic features of hydrocephalus vary depending on the age at onset, the rate of ventricular enlargement, and the degree of ventriculomegaly. Typically, elevated CSF pressure initially enlarges the frontal horns of the lateral ventricles, followed by enlargement of the entire ventricular system above the site of obstruction. Hydrocephalus is associated with flattening and destruction of the ventricular ependymal lining as well as edema and necrosis of the periventricular white matter.⁸² Periventricular glial cells proliferate, resulting in a layer of reactive gliosis. The pathologic

findings may be a result of reduction in blood flow to the white matter, causing hypoxic injury, and/or toxicity to the white matter due to the buildup of waste products not removed appropriately because of changes in the extracellular matrix.⁸³

In post-hemorrhagic hydrocephalus, high concentrations of proinflammatory cytokines,⁸⁴ free iron, and hypoxanthine,^{85,86} which can generate highly reactive radicals, have been measured in the CSF.

Separation of the ependymal lining of the ventricles enhances permeability, which increases the edema of adjacent white matter (transependymal fluid absorption). The expanding ventricles flatten the cerebral gyri and obliterate the sulci over the cortical surface. Unless the acute obstruction is relieved, the increasing pressure may hinder cerebral blood flow, cause cerebral herniation, and compromise brainstem function.

The increasing pressure and ventricular enlargement are associated with necrosis of the brain parenchyma. White matter is more vulnerable to destruction than cerebral gray matter in the presence of progressive hydrocephalus.^{87,88} The corpus callosum may also be preferentially affected, with evidence of transcallosal swelling, thickening, or demyelination.^{89,90} These effects do not appear to be associated with cognitive changes or neuropsychological evidence of callosal disconnection.

9.11 Management

The management of hydrocephalus is the most common problem in pediatric neurosurgery. In infants and children with symptomatic or progressive ventriculomegaly, the decision to treat with a CSF diversion procedure poses no therapeutic dilemma. However, not all patients with enlarged ventricles require treatment.

In patients with obstructive hydrocephalus secondary to a mass that is surgically accessible, resection of the mass may lead to resolution of the hydrocephalus, and a shunt may not be necessary. This situation occurs infrequently in comparison with communicating hydrocephalus. If no documented obstruction or operable lesion is present and the hydrocephalus is slight and slowly progressive, a trial period of observation or medical management may be indicated, especially in preterm infants.

Another situation in which observation is reasonable is arrested hydrocephalus, which is an uncommon state of chronic hydrocephalus in which the CSF pressure has returned to normal and there is no pressure gradient between the cerebral ventricles and the brain parenchyma. Patients should be followed carefully with neurologic examinations, neuropsychological assessments, and careful assessment of their development. A shunt will be necessary if there is any deterioration of those parameters.

Rapid-onset hydrocephalus with increased ICP is an emergency. Depending on the specific case, any of the following procedures can be performed: ventricular tap in infants; external ventricular drainage and lumbar puncture in post-hemorrhagic and post-meningitic hydrocephalus; endoscopic third ventriculostomy; and ventriculoperitoneal shunt.

The management of patients with in utero hydrocephalus remains controversial. Although the results of surgical attempts in

the 1980s were seen to be ineffective, interest remains as diagnostic technology and fetal surgery techniques advance.⁹¹ The recent Management of Myelomeningocele Study (MOMS), in which patients with a fetal diagnosis of myelomeningocele were randomized to either in utero closure or expectant treatment and postnatal closure, showed a significant increase in the requirement for CSF diversion, from 98 to 68%, albeit with the increased risk for preterm labor and maternal complications.⁹²

9.12 Prognosis

Before the 1950s, the outlook for patients with untreated hydrocephalus was extremely poor. Forty-nine percent of patients had died by the end of the 20-year observation period, and only 38% of survivors had an IQ greater than 85.⁹³ The development of satisfactory shunting substantially improved the outlook for patients with hydrocephalus but brought its own set of problems and complications. Most children with hydrocephalus require multiple shunt revisions. Shunt dependence carries with it an annual mortality rate of 1%.^{94,95} Another series, with 907 patients, reported a mortality rate of 12% at 10 years,⁹⁶ with the main risk factor for death being a history of shunt infection.

Shunt-related complications, including death, have been reported to be greater in patients with myelomeningocele than in those who required shunt placement for the treatment of other conditions.^{39,94}

The neurologic and intellectual disabilities of patients with hydrocephalus depend on many factors, including the etiology and severity of the hydrocephalus, thickness of the cortical mantle and corpus callosum,⁹⁷ requirement for a shunt, and presence of other brain anomalies.⁹⁸ Associated conditions, such as IVH, CNS infection,⁹⁶ and hypoxia, may dictate the ultimate prognosis more than the hydrocephalus.

A series of 233 patients with congenital hydrocephalus were evaluated for longer than 20 years; 13.7% died. The average number of shunt revisions was 2.7. In this series of 233 patients, of 115 who underwent psychological evaluation, approximately 63% showed normal performance, whereas 30% had mild retardation and 7% had severe retardation.⁹⁹ Another study found that children with congenital hydrocephalus were less likely to require special education placement (29%) than were those in whom hydrocephalus was due to meningitis (52%) or IVH (60%).¹⁰⁰

Epilepsy also is more prevalent among patients with hydrocephalus, and complications of shunt surgery appear to play a relatively minor role in its development.¹⁰¹

Intellectual sequelae include significant scatter among Wechsler Intelligence Scale for Children-Revised (WISC-R) subtest scores, often with greater impairment of performance and motor tasks, as well as of nonverbal compared with verbal skills.¹⁰² Normal intellectual function is present in 40 to 65% of patients who receive appropriate treatment.⁹⁸ The probability of normal intelligence is enhanced if shunts are placed early and proper function is maintained. A study of 99 children ranging in age from 6 to 13 years with shunted or arrested hydrocephalus demonstrated a close correlation between area of the corpus callosum affected and impairment of nonverbal cognitive skills and motor abilities.¹⁰³ Behavioral problems also are more common in children with hydrocephalus, irrespective of etiology.¹⁰⁴

9.13 Conclusion

Pediatric hydrocephalus is a common, complex, and in many ways poorly understood disorder. Although the persistent efforts to improve upon the treatments developed over the last century have had modest success, recent advances in imaging, neurophysiology, and molecular biology have led to important discoveries, suggesting that significant advances are imminent.

Pearls

- Hydrocephalus is a deceptively complex disorder, and simplistic explanations or theories have progressively fallen by the wayside.
- The arachnoid granulations are probably not the primary source of CSF absorption in humans—most likely the nasal lymphatics are.
- Try to establish the cause of hydrocephalus in all cases. It may affect treatment decision making, family counseling, prognosis, and outcome.
- Enlarged ventricles do not automatically invoke a shunt or third ventriculostomy. Be sure the risks of a lifelong commitment to an imperfect shunt device or the risks of a third ventriculostomy opening (and potential closure) are truly worth the benefits.

10 Treatment of Hydrocephalus with Shunts

Ricky Raj S. Kalra and John Kestle

Since the invention of the first implantable shunt valve by Nulsen and Spitz 60 years ago,¹ there have been innumerable innovations and new designs of shunt equipment to treat pediatric hydrocephalus. Shunts have made a dramatic impact on a previously devastating disease; however, despite the rational and seemingly more physiologic designs of these new devices, complications related to ventriculoperitoneal (VP) shunts continue to plague children with hydrocephalus. It is hoped that continued basic and clinical research will lead to advances in the management of pediatric hydrocephalus and improve the quality of life of affected children and their families.

10.1 Epidemiology

The management of hydrocephalus with cerebrospinal fluid (CSF) shunts is the most common neurosurgical problem encountered in the pediatric age group. Based on the Kids' Inpatient Database, the Hydrocephalus Clinical Research Network estimated 38,200 to 39,900 admissions, 391,000 to 433,000 hospital days, and total hospital charges of \$1.4 to \$2.0 billion for pediatric hydrocephalus.² Clearly, the treatment of hydrocephalus with shunts carries significant costs to patients, families, health care centers, and funding organizations.

10.2 Clinical Presentation

The various symptoms associated with hydrocephalus are discussed in Chapter 7. In this chapter, we discuss the criteria used in the determination of treatment for children with hydrocephalus, specifically in relation to CSF shunt insertion.

First-time shunt insertion is predominantly performed by pediatric neurosurgeons. In the International Society for Pediatric Neurosurgery (ISPN) database, 73% of patients who presented for first-time shunt insertion (774 patients) were 6 months of age or less at time of insertion.⁴ Furthermore, the median corrected age of patients entered in the Shunt Design Trial (SDT) was 55 days.⁵ In the endoscopic shunt insertion trial (ESIT), the median corrected age of patients was less than 3 months.⁶ The clinical characteristics of the patients undergoing first-time shunt insertion who were enrolled in SDT are outlined in ► Table 10.1 and ► Table 10.2. The most common causes for hydrocephalus were IVH, myelomeningocele, and brain tumors.

10.2.1 Diagnostic Tests

The decision to treat hydrocephalus is usually precipitated by the observation of ventricular enlargement. In the baby with an open fontanel, ultrasound will quite readily determine whether there is obvious ventriculomegaly. The addition of computed tomography (CT) or magnetic resonance (MR) imaging to the evaluation will vary depending on the center and the clinical characteristics of the patient being considered. Most surgeons prefer to obtain CT scans or MR images before shunt insertion to assess the morphology of the ventricles (including cysts and compartments) and the condition of the surrounding brain. The

exception is hydrocephalus associated with myelomeningocele; some surgeons will place shunts in these patients based on the ultrasound findings alone.⁵

Ventriculomegaly may be due to hydrocephalus or atrophy of surrounding brain tissue. The differentiation between these two conditions is crucial in deciding to place a shunt. Increasing head circumference or signs of raised intracranial pressure (ICP) make the differentiation straightforward. In more difficult cases, several imaging characteristics may help. The radiographic parameters that suggest hydrocephalus rather than atrophy include the following⁷:

- Dilated temporal horns
- Enlarged anterior and posterior recesses of the third ventricle
- Downward displacement of the floor of the third ventricle
- Dilatation and rounding of the frontal horns
- Effacement of the sulci
- Periventricular interstitial edema

In addition, inferiorly displaced cerebellar tonsils seen on sagittal MR imaging may indicate raised ICP.

10.3 Indications for a Shunt

Although the management of hydrocephalus is the most common clinical problem in pediatric neurosurgery, the decision to insert a shunt can be one of the most difficult. In the management of hydrocephalus and shunts, the old adage "If it ain't broke, don't fix it"⁸ is well worth keeping in mind.

Ventriculomegaly, either in a baby who presents with irritability, vomiting, a full fontanel, splayed sutures, and increasing head circumference or in an older child who presents with headache, vomiting, and papilledema, poses no therapeutic dilemma. Such children have raised ICP in need of treatment.

Other children, however, often present with milder symptoms and signs, or unimpressive imaging studies. In these patients, the decision is more difficult. Several terms are used to describe such children, and a wide range of recommendations can be gleaned from the literature. Some authors believe that asymptomatic mild or moderate ventriculomegaly does not need treatment. The definition of symptomatic, therefore, becomes very important; it is here that opinions vary. This is further complicated by the fact that the decision to place a shunt is often made when the child is very young (in the hope of maximizing cognitive development as the child grows and develops) and subtle cognitive problems are difficult to detect.

Fouyas et al used ICP monitoring to assess 18 patients previously without shunts ages 1 to 15 years (mean, 4.1 years) in whom the diagnosis of hydrocephalus was suspected but uncertain.⁹ The patients presented with developmental delay, deteriorating gait, increasing head circumference, headaches, irritability, or decreasing visual acuity. The clinical findings (examinations sometimes were repeated on several occasions) combined with ultrasound, CT, and MR imaging (done in some) had failed in all cases to reveal an unequivocal need for a shunt. ICP was elevated in 9 of 18 patients, and all of these patients improved symptomatically after shunt placement. The other nine patients had normal pressure and did not undergo shunt insertion. Three of them had a spontaneous resolution of symptoms with observation; the remaining six had persistent symptoms. Whittle et al reported the results of ICP monitoring in 46 children with a clinical and radiographic diagnosis of “arrested” hydrocephalus.¹⁰ The 16 patients that had never had shunts placed (ages 1 to 15 years; mean, 6.0 years) presented with either delayed milestones or decreased school performance ($n=4$), new or unstable seizure disorders ($n=6$), behavioral changes ($n=2$), or no symptoms (i.e., incidental finding; $n=4$). Of these 16 patients, 10 (69%) had elevated ICP. In a subset of children who underwent IQ testing, 2 of 5 with stable serial scores had elevated ICP, whereas 8 of 9 with falling scores had elevated ICP. The authors concluded that many patients with

apparent arrest of hydrocephalus in fact have an insidiously progressive disorder. Overall, however, ICP elevations were just as likely in the completely asymptomatic group as in the group with evidence of cortical dysfunction.

McLone et al defined compensated hydrocephalus as untreated hydrocephalus that is clinically and radiographically stable.^{11,12} In such patients, a variety of imaging studies and invasive tests (e.g., infusion tests, radionuclide studies, ICP monitoring, and Doppler imaging) have been proposed to differentiate which children with apparently asymptomatic ventricular enlargement would benefit from shunt placement. Children who are older than 5 years with a stable clinical course and ventricle size may be monitored without a shunt, but they do require frequent testing of their intellectual development. Children who are younger than 5 years old, particularly those younger than 3 years old, who have anything more than mild hydrocephalus should have shunts placed. This younger group is difficult to assess for intellectual development, and mere attainment of developmental milestones is insufficient to determine ultimate intellectual function.^{11,12} Measurement of opening pressure may be helpful in some cases.

Dias et al conducted a survey study to analyze the threshold for pediatric neurosurgeons to place shunts in asymptomatic children with ventriculomegaly.¹³ The majority of respondents, who represented approximately 25% of full-time practicing pediatric neurosurgeons in North America, considered themselves relatively conservative when it came to shunt placement. Across the 22 scenarios presented, however, there was significant variability in the responses to certain cases, especially those in which developmental delays and head circumference were considered abnormal. The study concluded that the overall threshold for shunt placement was high, but significant treatment variability existed when it came to vague cases.

MR spectroscopy has been suggested as a method of differentiating atrophy from hydrocephalus. Brain lactate levels were more commonly elevated and ratios of *N*-acetyl aspartate to creatine were lower in children with atrophy than in those with

hydrocephalus; however, three of five patients in the atrophic group had inborn errors of metabolism, possibly accounting for some of the metabolic abnormalities seen.¹⁴

Preterm infants with IVH pose another dilemma in regard to CSF diversion. There are few randomized studies to support surgical indications for temporizing devices, such as reservoirs and subgaleal shunts, and similarly limited data for shunt placement. Riva-Cambrin et al analyzed four large pediatric centers to determine whether clinical and radiologic factors influenced practice patterns and treatment modalities.¹⁵ The study evaluated 110 neonates with grade 3 or 4 IVH treated surgically. Thirty-seven patients underwent permanent shunt placement at a mean gestational age of 39.5 weeks. Seventy-three patients (66%) were treated with temporizing devices, and in 65 (89%) of those, the temporizing devices were converted to permanent shunts. The only factors statistically significant in determining placement of a temporizing device were bradycardia episodes, full fontanel, and splayed cranial sutures. Factors associated with conversion to a shunt included a full fontanel and increased ventricular size. Overall, no clear factors aside from bradycardia and ventriculomegaly were significant in determining conversion of temporary to permanent implants. Furthermore, the authors described a “center effect” in determining whether patients underwent a temporizing procedure.

In summary, particularly difficult cases may require ICP monitoring or other adjunctive tests in the assessment of possible hydrocephalus, but in most children, the decision can be based on observation over time. Documentation of a progressive pro-

blem is a key factor in the decision (► Fig. 10.1). This may include progressive developmental or cognitive delay. The most difficult decision is in the young child with compensated hydrocephalus and moderate to severe ventriculomegaly. Further research in this group of children is needed. Additionally, there is significant variability among surgeons and centers in treatment modalities and practice patterns, and thus a greater effort must be devoted to establishing treatment protocols based on randomized and well-evaluated data.

10.3.1 Disease-Specific Considerations Posttraumatic Ventriculomegaly

What is the best management of a 13-year-old child who, after experiencing a closed head injury at 10 years of age, has a history of development delay and MR images showing enlarged ventricles? The child’s rehabilitation physician asks whether a shunt would facilitate recovery. This case presents a rare complication of head injury in pediatrics; however, it is a good example of a case that requires the differentiation of atrophy from hydrocephalus.

Marmarou et al monitored 75 patients whose head injuries resulted in a Glasgow Coma Scale (GCS) score of 8 or less.¹⁶ According to the size of the frontal horns, the ICP, and the resistance to CSF absorption (measured with a lumbar infusion test), the authors classified patients as having normal ICP, benign intracranial hypertension, atrophy, normal-pressure hydrocephalus, or high-pressure hydrocephalus. They advocated placing

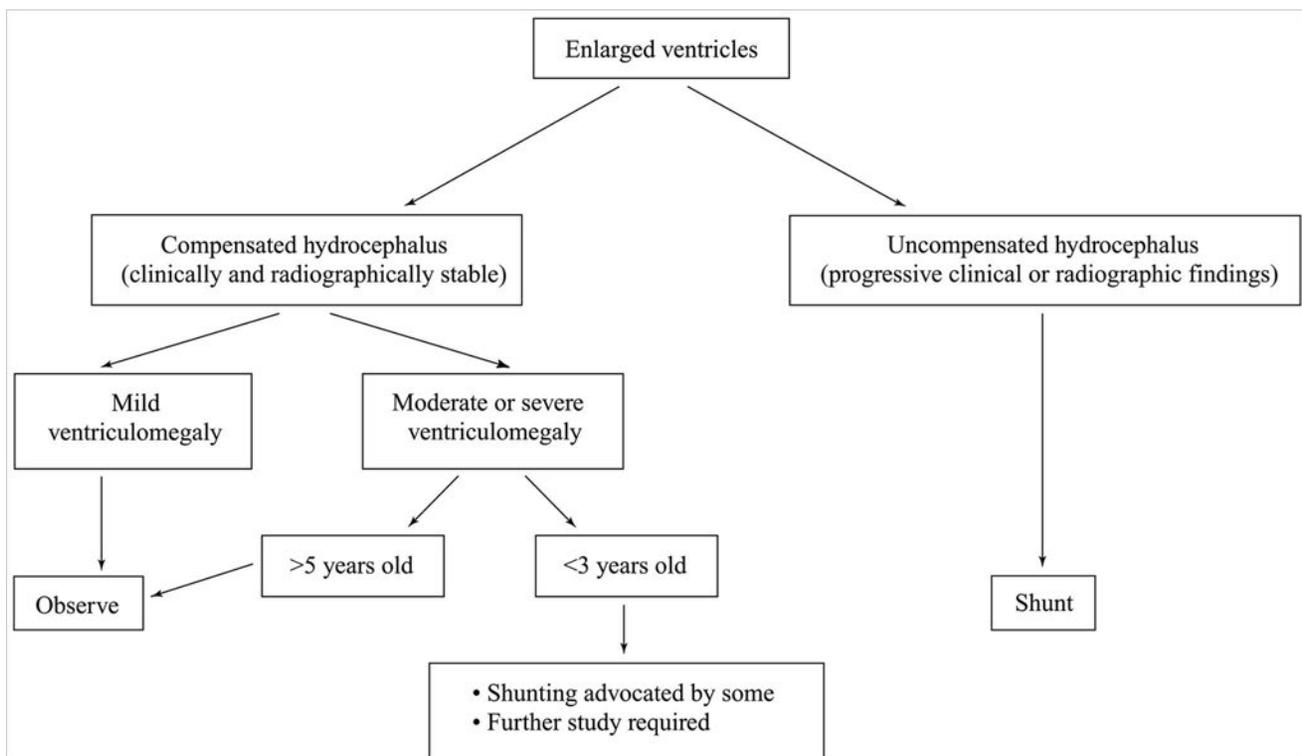

Fig. 10.1 Selection of patients for shunt insertion. (From Kestle JRW, Garton HJL, Drake JM. Treatment of hydrocephalus with shunts. In: Albright L, Pollack I, Adelson D, eds. Principles and Practice of Pediatric Neurosurgery. New York, NY: Thieme Medical Publishers; 1999:75–91.94 Republished with permission.)

shunts in patients in the last two groups; 4 of 15 such patients had shunts placed. All four improved one level on the GCS. In their patients, distention of the temporal horns or third ventricle and periventricular lucency were not specific for hydrocephalus (as they defined it). Subarachnoid hemorrhage on the baseline scan was more common (70% vs. 16%) in patients with hydrocephalus.

Posterior Fossa Tumor

Routine preoperative shunt placement in patients with tumor is no longer common practice because many patients remain shunt-free after tumor removal. Dias and Albright reported a series of 58 patients with posterior fossa tumors and hydrocephalus.¹⁷ Of these, 25 had shunts placed preoperatively, 17 had external ventricular drains (EVDs), and 16 had no preoperative ventricular catheterization. Of the 33 patients without preoperative shunt placement, 24 remained shunt-free at long-term follow-up. When a Cox regression model was used, two factors were associated with shunt insertion: subtotal tumor resection and incomplete dural closure at surgery.

Lee et al studied 42 children (younger than 20 years old) with newly diagnosed posterior fossa primitive neuroectodermal tumors who did not have shunts at the time of surgery and who survived the perioperative period.¹⁸ Of these, 17 (40%) required a shunt by 4 weeks postoperatively, and an additional 2 patients required late shunt placement at the time of tumor recurrence. The group with shunts was younger (5.4 years vs. 10 years), had more severe hydrocephalus, and had more extensive tumor.

At present, a shunt should be withheld in the preoperative phase unless a significant delay between presentation and surgery is expected. Even then, a temporary EVD or a third ventriculostomy may be preferable to a shunt. Many children with a posterior fossa tumor have resolution of their hydrocephalus with tumor removal alone.

At Primary Children's Medical Center, our practice is to insert an EVD at the time of tumor removal. We avoid placing ventricular drains before surgery because of the risk for upward herniation. If the patient's clinical condition requires immediate placement of an EVD, our practice is to proceed with tumor removal at that time. The drain is left at 10 to 15 cm above the head for the first 48 hours postoperatively. The EVD is then gradually elevated over the next 3 to 5 days, clamped, and removed if the child remains well. CT to assess ventricular size with the drain clamped is often useful just before EVD removal.

Sainte-Rose et al have reported their results of the management of hydrocephalus in a consecutive group of 206 children with posterior fossa tumors.¹⁹ Only 4 of 67 patients (6%) who underwent preoperative third ventriculostomy developed progressive hydrocephalus requiring treatment, compared with 22 of 82 patients (28%) who had conventional treatment preoperatively. This is interesting but in our opinion does not justify the risk of doing a preoperative third ventriculostomy in all patients with posterior fossa tumor because a significant number will not need any treatment for hydrocephalus. An endoscopic third ventriculostomy may be considered for patients who appear drain-dependent after tumor removal, but in our experience, most of these patients eventually require a VP shunt.

Riva-Cambrin et al reported a model for assessing the risk of developing hydrocephalus in pediatric patients with posterior

fossa tumors.²⁰ They examined 343 patients with posterior fossa neoplasms and identified predictors of hydrocephalus at 6 months after resection. The preoperative predictors included in the model were age less than 2 years, presence of papilledema, preoperative moderate or severe hydrocephalus, cerebral metastasis, and tumor pathology. A probability scale was developed and validated to predict the need for CSF diversion based on the number of preoperative predictors present.

Myelomeningocele

Several studies are available regarding the timing of shunt placement in children with a myelomeningocele. The reported advantages of simultaneous shunt insertion and back closure are a shorter hospital stay and a decreased incidence of back wound problems.²¹ The disadvantages of simultaneous surgery are increases in the infection rate and the failure rate of the shunt. There is also the risk of committing some children to a shunt who may have not needed one. At present, both approaches are used, and a clear advantage of one over the other has not been demonstrated.

Caldarelli et al compared simultaneous shunt placement with delayed shunt placement in 89 children with myelomeningocele treated between 1980 and 1994.²² The 1-year failure rates in the simultaneous and delayed shunt insertion groups were 31% and 47%, respectively; infection rates were 23% and 7%. Six patients had a shunt inserted first and underwent delayed back closure; 5 of them (83%) had a shunt infection. At the University of Pittsburgh, 69 patients with myelomeningocele underwent back closure and either simultaneous ($n=21$) or delayed ($n=48$) shunt placement between 1987 and 1993.²¹ The two groups were similar in terms of head circumference, but no other comparative information was given. There were 8 children with CSF leak from the lumbar wound in the delayed group and none in the simultaneous group. The rate of obstruction, however, was higher in the simultaneous group, so the overall complication rate was not significantly different between the groups. The infection rate was not different between the groups (1 of 21 and 2 of 48). The authors concluded that simultaneous repair led to shorter hospitalizations and lower rates of back wound morbidity.

Adzick et al published a landmark study comparing prenatal and postnatal repair of myelomeningoceles in regard to primary outcomes, including mortality and the need for a CSF shunt.²³ They reported that 40% of infants who underwent intrauterine closure of the myelomeningocele required shunt placement by 12 months, whereas 82% of the patients who underwent postnatal repair required a shunt by 12 months. The study concluded that prenatal closure of myelomeningocele increased fetal, pregnancy, and delivery risk but resulted in a lower need for shunt placement. Secondary outcomes also showed improved motor scores for patients with intrauterine repair.

10.3.2 Shunt Versus Third Ventriculostomy

Once a diagnosis of hydrocephalus has been made and treatment is required, a choice must be made between a shunt and a third ventriculostomy. As is discussed in the next chapter, on neuroen-

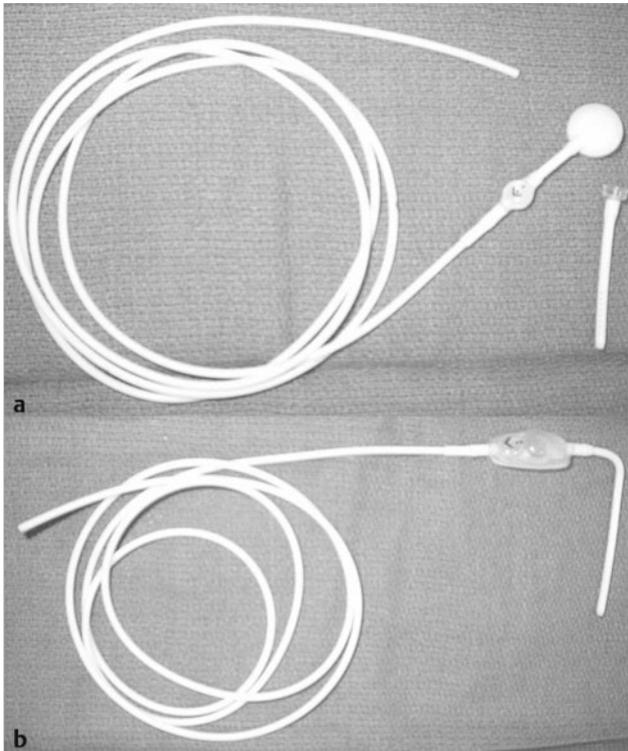

Fig. 10.2 Shunt systems typically contain three parts: a ventricular catheter, a valve with or without a reservoir, and distal tubing. (a) They are available as separate components or (b) unitized.

doscopy, several patients with previously placed shunts are now being treated with endoscopic third ventriculostomy. Ideal patients for third ventriculostomy have evidence of noncommunicating, or obstructive, hydrocephalus and preservation of CSF absorption. Unfortunately, patient selection remains a challenge because there is no simple, noninvasive test to assess the adequacy of CSF absorption. In general, patients who have late-onset hydrocephalus from aqueductal stenosis do the best after third ventriculostomy, presumably because they had normal CSF absorption before blockage at the aqueduct. The surgical goal is to create an opening in the floor of the third ventricle between the infundibular recess and the mammillary bodies. This creates a free-flowing communication between the ventricular system and the basal subarachnoid spaces. Endoscopic third ventriculostomy is an option for about a quarter of children with hydrocephalus. The remaining majority, however, will still require a shunt.

10.4 Equipment

VP shunts are composed of three basic elements: a ventricular catheter, a valve, and a peritoneal catheter (► Fig. 10.2). There are many variations of each of these components available on the market.

10.4.1 Ventricular Catheter

Barium-impregnated Silastic (Dow Corning, Midland, MI) tubes that enter the ventricle are available in several configurations.

Several transverse diameters are available, but the difference is primarily in the wall thickness because the internal diameters are almost identical. Right-angled ventricular catheters are also available, but they are somewhat limiting because the intracranial length is fixed. If right-angled catheters are used, it is necessary to have several catheters of different lengths available for different clinical situations. Ventricular catheters with flanged tips were thought to minimize proximal obstruction, but this has not been supported in the literature.^{24,25}

Another consideration is whether the ventricular catheter should be a separate or integral part of the valve mechanism. When the ventricular catheter is inserted, if bleeding occurs, it is best to allow drainage of fluid through the ventricular catheter before attaching it to the valve. With an integral ventricular catheter and valve, this is not possible; the blood and cellular debris can occlude the valve immediately. For this reason, we use a separate ventricular catheter.

Recent advances in ventricular catheter development have included antibiotic-impregnated proximal catheters. In prospective trials, the clindamycin- and rifampin-impregnated catheters (Bactiseal; Codman & Shurtleff, Raynham, MA) have been shown to provide antistaphylococcal coverage.

10.4.2 Valves

As outlined previously, most modern valves can be grouped into one of several categories based on their hydrodynamic characteristics^{24,26}: differential-pressure valves, siphon-resisting valves, flow-regulating valves, and adjustable valves (► Fig. 10.3 and ► Fig. 10.4).

Differential-Pressure Valves

Differential-pressure valves have been available longer than the other valves, and surgeons have accumulated the most experience with this type of valve. These valves open when the pressure difference across the valve exceeds a predetermined threshold. The valve then remains open, and during this time it has a very low resistance to flow. When the pressure difference drops below the predetermined threshold, the valve closes again and flow stops. When the patient is in the upright position, a large differential pressure between the head and the abdomen develops from the long column of water in the shunt tubing. The valve therefore opens, and fluid flows until the pressure in the head is excessively negative.²⁷ This phenomenon is called siphoning, and it is thought to be responsible for overdrainage and its associated complications (► Fig. 10.5).

Differential-pressure valves are available with low, medium, and high opening pressures. In general, low-, medium-, and high-pressure valves refer to opening pressures of approximately 5, 10, and 15 cm H₂O, respectively. Unfortunately, however, there are no uniform standards for these designations, and the manner in which the pressure is measured is variable. Furthermore, the large column of fluid and the associated negative pressure overwhelm the differences among these three pressures when the patient assumes the upright position. Drake and Sainte-Rose have reviewed the many brands and configurations of differential-pressure valves.²⁴

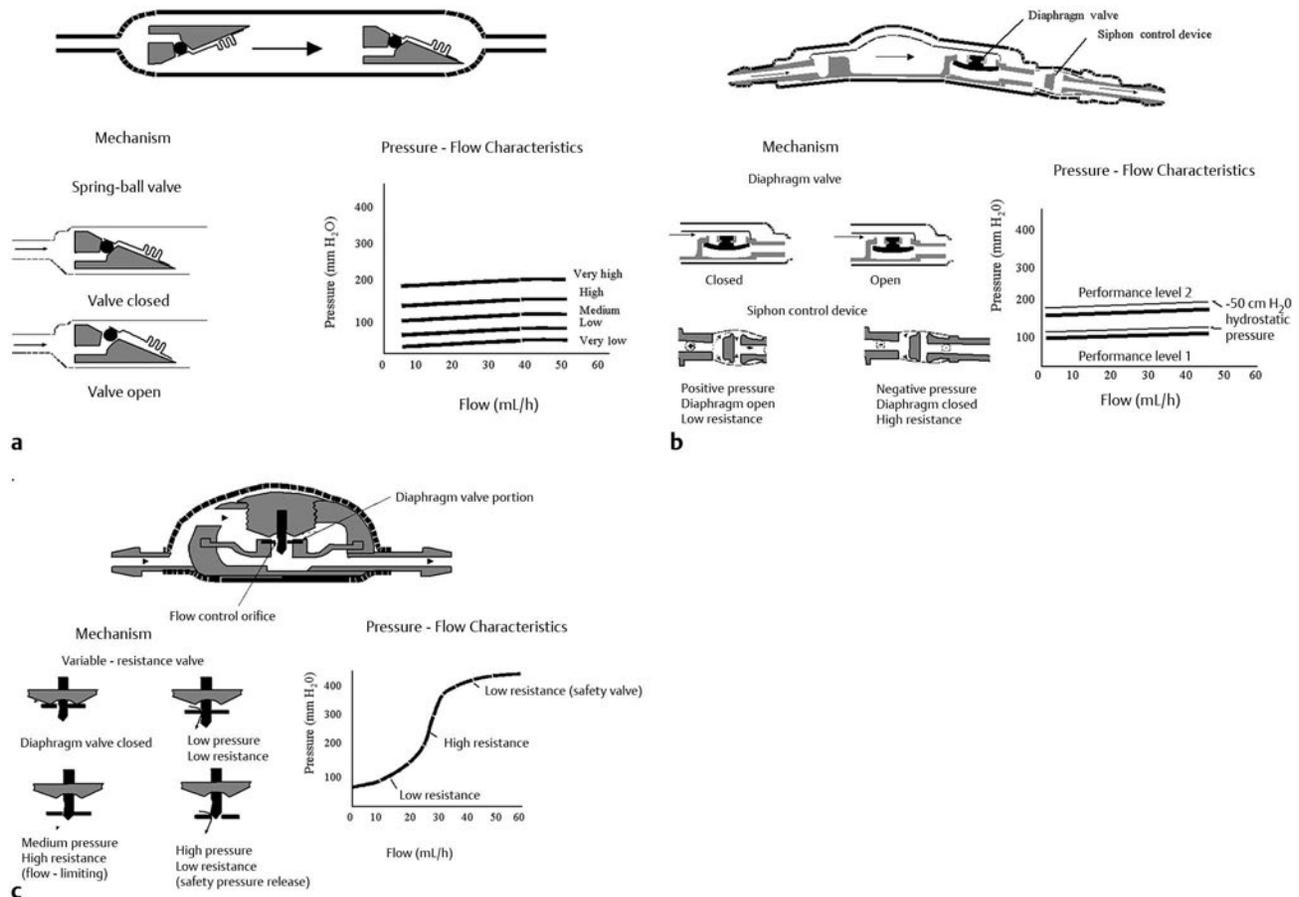

Fig. 10.3 Standard shunt valve designs. In a standard differential-pressure valve (a), flow increases rapidly once the opening pressure is exceeded. The PS Medical Delta (Medtronic Neurosurgical) valve (b) consists of a standard differential-pressure valve (diaphragm type) followed by an antisiphon device to reduce the effects of gravity when the patient is upright. The Orbis Sigma (Cordis Corporation) valve (c) is a flow-limiting valve. (From Drake JM, Kestle JRW. Determining the best cerebrospinal fluid shunt valve design: the pediatric valve design trial. *Neurosurgery* 1996;38:605. Republished with permission.)

Siphon-Resisting Valves

The Delta valves (Medtronic Neurosurgical, Goleta, CA) contain a device that is designed to reduce flow as the patient assumes the upright position (i.e., when siphoning occurs). Similar mechanisms are available as separate components that can be added to other shunt systems (e.g., Mueller Heyer-Schulte anti-siphon device [Integra, Plainsboro, NJ] and Medtronic Neurosurgical siphon control device).

Flow-Regulating Valves

The Orbis Sigma valve (Cordis Corporation, Bridgewater, NJ) consists of a flexible diaphragm that moves along a piston of variable diameter, resulting in three pressure flow stages. In stage 1, the valve functions like a differential-pressure valve. In stage 2, as the ventricular pressure increases, the diaphragm descends along the piston, whose diameter progressively enlarges. This reduces the flow orifice and dramatically increases the resistance to flow. A very small increase in the flow rate results despite a progressive increase in pressure. In stage 3, a high-pressure safety release mechanism results in open flow

when the pressure in the ventricular catheter reaches approximately 40 cm H₂O. The diaphragm at this point is beyond the end of the piston and resistance is very low.

Externally Adjustable Valves

More recently developed shunt systems have incorporated an adjustable valve, which enables the surgeon to make non-invasive alterations in the valve's pressure-flow profile as the patient's clinical course changes.²⁸⁻³³ Unlike traditional valves, however, programmable valves may be percutaneously adjusted with an external magnet or a special programming tool that works via a magnetic field.^{34,35} This may be advantageous in patients with normal-pressure hydrocephalus, in patients with arachnoid cysts, and in patients with complications caused by acute or chronic overdrainage, such as subdural hygromas, chronic subdural hematomas, and slit-ventricle syndrome (SVS).³⁶ In pediatric patients, closure of the sutures, attainment of erect posture, growth, and aging are all additional situations in which the opening pressure of the valve may require adjustment.³³ A randomized clinical trial did not demonstrate any survival benefit of the

Codman-Medos programmable valve (Codman & Shurtleff) over standard valves.³⁷ In a prospective study examining the Strata valve (Medtronic Neurosurgical), 315 patients undergoing first shunt insertion ($n=201$) or shunt revision ($n=114$) received the valve. One-year shunt survival after first insertion was 68% and after shunt revision was 71%. These shunt survival data are similar to those published for other valves. Valve adjustments resulted in complete resolution of symptoms in 26% of the patients and an improvement in the symptoms of 37% of the patients. When symptoms improved or resolved, they did so within 24 hours in 89% of the adjustments that were made.³⁸ Although a clear advantage to adjustability has not yet been demonstrated in terms of shunt survival, many surgeons find this feature desirable in an attempt to relieve symptoms, maintain large ventricles, or deal with small fluid collections (► Fig. 10.6). The ability to adjust the valve pressure non-invasively, and thus potentially minimize subsequent operative manipulations of the shunt system, may warrant the increased expense and complexity of the programmable system.^{28,33,35,37}

10.4.3 Reservoir

A reservoir is very commonly used; it may be incorporated as part of the valve or added separately. It is usually placed near the valve or at the bur hole. It is useful for access to the CSF for

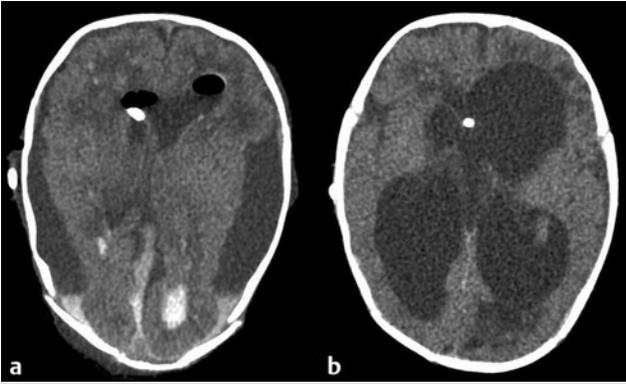

Fig. 10.6 (a) Subdural collections caused by overdrainage (b) can often be managed successfully by percutaneously increasing the valve pressure of a programmable valve until the subdural collections have resolved.

diagnosis of infection and occasionally for removal (or attempted removal) of CSF in emergent situations.

10.4.4 Peritoneal Catheter

Peritoneal catheters are also made of Silastic and impregnated with barium to make them radiopaque. The length is suitable for adult insertion, but the catheter can be shortened for use in children if necessary. In most cases, a full-term baby can accept nearly the full length, so elective lengthening is unlikely to be necessary. The catheters have an open distal end, and some have distal ports on the side. Peritoneal catheters are also available with a closed distal end and slits in the side of the tubing (distal-slit valves), which function in a differential-pressure fashion. In a review of 1,719 patients from Toronto and Paris, Sainte-Rose et al found that distal slit valves had a significantly higher failure rate than proximal non-slit valves.²⁵

10.4.5 Antibiotic-Impregnated Shunt Systems

Antibiotic-impregnated shunt (AIS) systems are designed to reduce bacterial colonization and the risk for infection. An AIS system was evaluated in a prospective, randomized clinical trial to determine whether it reduced the incidence of shunt infections compared with standard shunts. After a median follow-up of 9 months, 10 of 60 patients in the control group and 3 of 50 in the AIS group developed infections ($p=0.08$).³⁹ Parker et al published a systematic literature review with 12 studies comparing AIS and non-AIS systems.⁴⁰ Across these studies, 5,613 patients were identified with reported shunt procedures: 2,664 patients who received AIS systems and 2,949 patients who did not. The rate of shunt infection in pooled AIS patients was 3.3%, whereas the non-AIS patients had a rate of 7.2% (odds ratio [OR], 0.439; $p<0.0001$). These data favor the use of AIS systems; however, large randomized, prospective studies are needed to truly ascertain the absolute risk reduction obtained by using AIS systems.

10.4.6 Choosing the Appropriate Equipment

The amount of evidence that is available for choosing shunt equipment is limited. Probably the best advice is for a surgeon to become familiar with one system and use it consistently. Our preference is to use a straight ventricular catheter with a snap-on reservoir. A ventricular catheter integrated into the valve is not used, so that blood and debris can be drained away before the ventricular catheter is hooked up to the valve. An open-ended peritoneal catheter may or may not be integrated with the valve. A reservoir may be used as part of the valve system for access to CSF.

The choice of a valve has commonly been an area of great interest and controversy. A multicenter trial has compared a standard differential-pressure valve, a siphon-resisting valve (Delta valve; Medtronic Neurosurgical), and a flow-regulating valve (Orbis Sigma valve; Cordis Corporation) for children with newly diagnosed hydrocephalus.⁵ No significant difference was found in the time to first shunt failure among the three systems (► Fig. 10.7). Furthermore, as previously mentioned, clinical studies have not demonstrated a significant survival benefit for the adjustable valves (► Fig. 10.8 and ► Fig. 10.9) compared with standard valves.³⁷

10.5 Surgical Technique

10.5.1 Positioning

In the operating room, the patient is positioned under general anesthesia with the head rotated to the side opposite the proposed shunt. The neck should be extended with a bolster under the neck and shoulder so that there is almost a straight line between the scalp and abdominal incisions (► Fig. 10.10). Several studies have shown that prophylactic antibiotics covering skin organisms are effective⁴¹; therefore, they are strongly recommended.

10.5.2 Ventricular Catheter Placement Head Entry Site

The ventricular catheter may be inserted through a posterior parietal or a coronal bur hole. The relative merits of the two have been debated in the past. Data from a nonrandomized study with 10-year follow-up suggested better shunt function after coronal placement.⁴² In a randomized trial comparing these two entry sites,⁴³ 59% of the shunts inserted through an anterior bur hole continued to function at 14-month follow-up compared with 70% of shunts inserted through a posterior bur hole. This difference was not statistically significant, however, and the authors concluded that anterior placement did not offer any advantage over posterior placement. Anterior placement has been supported by some surgeons as the preferable method when endoscopic insertion is being performed. An anterior approach may allow better visualization of the foramen of Monro and catheter placement through an intraluminal endoscope. Its disadvantage is that it usually requires an additional skin incision behind the ear because it is difficult to make a direct

subcutaneous tract from the coronal incision to the site of the distal catheter.

Traditionally, the hair in the area of the cranial incision has been shaved or clipped. Shaveless shunt surgery has been reported, however, in which little or no hair is cut. The hair is washed, prepared, and left in the operative field. The experience is small, but infection has not been a significant problem.⁴⁴ The scalp incision should be placed such that the shunt hardware does not lie directly underneath it, particularly in younger patients with thin scalps. This helps to reduce the risk for erosion of the shunt through the incision. If a linear incision is desirable, it should be of sufficient length

that the tissue can be retracted and the bur hole made medial or lateral to the incision. A curvilinear incision is another possible option.

When the opening in the dura is being made, care should be taken to make the opening just large enough to allow passage of the ventricular catheter. This will decrease the chance of CSF leak around the tubing. One method to create a small dural opening is to place a small brain needle against the dura and apply low-intensity monopolar coagulation to the needle.

Location of the Tip

To minimize the chances of proximal obstruction, the ventricular catheter tip should be placed away from the choroid plexus. Most surgeons choose the frontal horn, but based on their review, Sainte-Rose et al noted that the likelihood of ventricular catheter obstruction is lower when the catheter is placed posteriorly in the atrium of the ventricle via an occipital route.²⁵

In a randomized trial, Steinbok and colleagues compared ipsilateral and contralateral placement of the ventricular catheter in the ventricular system.⁴⁵ When the surgeon's intention was to place the catheter in the contralateral ventricle, 29% of patients developed ventricular asymmetry, whereas 48% of patients with ipsilateral placement developed asymmetry. When the analysis was based on the final location of the catheter (despite the surgeon's intentions), asymmetry was seen in 23% of the contralateral catheters and 54% of the ipsilateral catheters. There was no difference, however, in the shunt revision rate in the two groups.

In ESIT, there was no difference in shunt survival with or without endoscopic insertion.⁶ When the results were analyzed based on the final position of the catheter tip on postoperative imaging, it appeared that a location away from the choroid plexus was important in maintaining shunt function. Unfortunately, it did not appear that this was accomplished with the endoscope (► Fig. 10.11).

Loculate Hydrocephalus

Loculate hydrocephalus occurs when the ventricular system becomes obstructed by septa or cysts that develop congenitally or after hemorrhage, infection, or surgical trauma. This relatively uncommon entity is particularly difficult to deal with, as there can be numerous septa within the ventricular system that inhibit the drainage of CSF. Affected children sometimes end up with multiple intracranial catheters and/or multiple shunt systems. Complex shunt systems (incorporating three-way connectors or consisting of multiple linear shunt systems) have been shown to have a much higher failure rate than simple, linear shunts.⁴⁶

With the currently available endoscopic equipment, it is often advantageous to attempt fenestration of the septa or the septum pellucidum to allow communication between the locular compartments. Endoscopic fenestration can help reduce the rate of shunt revision, simplify existing shunt systems, and, in some cases, even avoid placement of shunts. When the experience with septal fenestration at Primary Children's Medical Center was retrospectively reviewed, 43 septostomies were performed in 32 patients over an 8-year period.⁴⁷ At a mean follow-up of 31 months, 81% of children had relief of their isolated lateral ventricle, with no septostomies failing after 6 months postoperatively. A prior history of multiple shunt procedures was highly predictive of initial septostomy failure, however, increasing this risk by 4.5. In some cases, successful endoscopic fenestration may require multiple fenestration procedures.

Before endoscopic fenestration is undertaken in multiloculate hydrocephalus, optimal radiographic imaging is essential to define anatomical and functional relationships between the cysts and the ventricular system. MR imaging provides the necessary

anatomical detail, but a CT dye study remains the best preoperative imaging study to verify lack of communication with the ventricular system and delineate to CSF compartments.

10.5.3 Adjuncts to Placement

Ultrasound

In a child with an open fontanel, ultrasound provides an excellent means by which to visualize the ventricular system and to observe the ventricular catheter as it is being inserted. A small amount of movement of the catheter is sometimes helpful; when this is done, the surgeon can usually identify the position of the catheter with respect to the ventricular system. There is some inconvenience in having to bring the ultrasound system into the operating room to perform the imaging; however, with practice it does not add much time to the procedure.

Endoscopy

Endoscopes are now available that fit into the lumen of the ventricular catheter. These allow visualization of the ventricular system as the catheter is being inserted. The goal when such equipment is used is to place the catheter away from the choroid plexus, which is thought to decrease the incidence of obstruction. Contrary to the results of several uncontrolled, retrospective case series,^{48,49} the multicenter, randomized, controlled ESIT demonstrated that, compared with standard placement, endoscopic placement of the ventricular catheter does not reduce the incidence of shunt failure in children undergoing initial VP shunt insertions (► Fig. 10.11).⁶ It is important to remember, however, that this trial did not evaluate the utility of the endoscope in shunt revisions. At Primary Children's Medical Center, we continue to use the endoscope frequently with shunt revisions because we believe the endoscope can be very helpful in situations of complex ventricular anatomy to confirm catheter placement within the ventricular system.

During placement of an endoscope, care should be taken not to change the angle of trajectory of the scope after it goes through the mantle of brain tissue. If this is done to get the catheter tip in a desired position, the catheter will probably move when the endoscope is removed and the deformed cerebral mantle will return to its baseline position.

10.5.4 Distal Catheter Placement

Peritoneum

The peritoneum is the preferred location of the distal catheter and the most commonly used. The rationale for this preference is that it is technically easy to gain access to the peritoneal cavity, and the peritoneum is extremely effective in absorbing CSF. It may be accessed via an open, small laparotomy and opened for catheter placement. A purse-string suture is placed around the catheter as it enters the peritoneum. Alternatively, an abdominal trocar through a paramedian incision can be used for peritoneal placement. We prefer to use a trocar because it is much faster, requires a small incision, and induces fewer adhesions at the site of entry. The disadvantages include a slightly higher risk for preperitoneal placement and vascular or visceral injury.⁵⁰ A trocar was used in 169 (23%) of 764 cases surveyed

by Di Rocco et al; abdominal complications were rare with either method.⁴⁵ As previously mentioned, the full length of an adult peritoneal catheter can usually be inserted in the full-term baby to allow for growth and to avoid a lengthening procedure.

Patients with multiple previous abdominal surgeries or morbid obesity present a unique challenge when the distal catheter is inserted into the peritoneum. At our institution, we consult general surgeons for laparoscopically assisted peritoneal shunt insertion in such patients. Laparoscopic insertion is a safe and effective way of placing the catheter into the peritoneum under direct visualization, with minimal risk for damage to the abdominal viscera. Additionally, placement of the distal catheter into the preperitoneal space in morbidly obese patients can be avoided with this technique.⁵¹

Alternate Distal Sites

It is very unusual that the peritoneum cannot be used for distal shunt insertion. Children with multiple abdominal operations, active abdominal infection (including necrotizing enterocolitis in preterm infants), or chronically elevated intra-abdominal pressure may require extraperitoneal shunt insertion. Choosing among the alternative sites depends on the clinical situation. In general, the second choice is usually the heart or the pleural space. In patients who have had multiple central venous catheters placed previously, it is often helpful to obtain an ultrasound preoperatively to confirm the patency of the venous system and to help determine which vein to use for access to the heart. The pleural space should be avoided in young children and children with lung disease. The gallbladder is a site that is used less frequently.⁵² A transdiaphragmatic insertion of a shunt into the subphrenic space has been reported.⁵³

Atrium

The technique of atrial insertion has been well described.⁵⁴ Access to the venous system can be achieved through an open or a percutaneous approach. Intraoperative fluoroscopy is used to position the distal catheter around the T6 level. A shunt system that incorporates a one-way valve must be used to prevent backflow of venous blood into the intracranial ventricular system.

With the high incidence of long-term complications, distal shunt insertion into the atrium should be considered a temporary alternative; every attempt should be made to remove the catheter from the venous system and replace it in the peritoneum or in the pleural space as the child grows. In one large series, two-thirds of revisions in 120 patients over an average follow-up of 11 years were performed to lengthen the catheter, whereas 8% of revisions were performed for distal obstruction.⁵⁵

Pleural Cavity

It has been asserted that pleural shunting is poorly tolerated in young children because of a lack of absorptive pleural surface, but the literature contains conflicting information. In a series by Piatt, one-third of infants required treatment for pleural effusions, although the treatment consisted of intermittent thoracentesis rather than shunt revision.⁵⁶ Only 2 of 19 older

patients, however, developed effusions. Various authors have recommended pleural shunting in successively lower age groups, and temporary use has been recommended even in children younger than 12 months of age.⁵⁷

Perhaps a more important contraindication than age is coexisting pulmonary dysfunction. Kyphoscoliosis, present in many patients with myelomeningocele, is one common condition limiting ventilatory reserve. In Piatt's series, 2 of 6 patients with myelomeningocele had symptomatic effusions, compared with none of the 16 remaining patients.⁵⁶ Both Piatt and Jones et al supported the use of siphon-restricting devices to avoid overdrainage.^{56,58} Although the negative pleural pressure can theoretically cause siphoning, no study has shown a significant improvement in pleural shunt survival with siphon-resisting devices.

Case-control and other published studies have not shown a difference between shunt survival rates for peritoneal and pleural shunts.⁵⁶ A pleural shunt may be a good choice when logistics require shunt placement with the patient in the prone position.

The distal catheter is inserted into the pleural cavity with a trocar. A small incision is made over a rib in the anterior or posterior axillary line. The trocar can then be advanced directly over the top of the rib into the pleural space, and the distal catheter is passed through the trocar. Continuous irrigation should be used to minimize the risk for a pneumothorax, but even if it is used, a postoperative chest X-ray should be checked for a pneumothorax.

Gallbladder

West et al reported a series of 25 patients with ventricle-gallbladder shunts.⁵⁹ Shunts were functional in 14 (70%) of the 20 patients with long-term follow-up. There were three early shunt failures: two due to proximal obstruction and one due to gallbladder atony (treated with cholecystokinin). Reflux of bile into the ventricular system has been reported in association with one patient's death.⁶⁰

10.5.5 Postoperative Care

Postoperatively, children are usually placed with the head slightly elevated. Sainte-Rose et al recommended wrapping the head with light compression to the cranial wound to minimize the collection of CSF around the shunt in the early postoperative days.²⁵ We do not routinely wrap the head after shunt insertions or revisions, and we have not had significant problems with subgaleal collections. Most surgeons monitor patients for 24 to 48 hours after a first-time shunt insertion to ensure the anterior fontanel is down and the wounds are healing before discharge. We routinely order CT of the head and a shunt series before discharge to ensure shunt hardware continuity and to have immediate baseline images for future comparison. We do not routinely administer antibiotics postoperatively.

Recently published data by Pearce et al suggest that the use of CT in children significantly increases the risk for leukemia and brain tumors.⁶¹ The analysis shows that the radiation doses from 2 to 3 CTs of the head in patients younger than 15 years of age triple the risk for brain tumors, and that the

radiation doses from 5 to 10 CTs of the head triple the risk for leukemia. In the population of pediatric patients with hydrocephalus, CT of the head is performed routinely after shunt surgery, often in the emergency department setting in cases of suspected shunt malfunction. At our institution, we are developing protocols to reduce the amount of radiation patients receive, both by improving education in the emergency department in regard to which patients require CT of the head for hydrocephalus and by not routinely ordering CT of the head for patients who clinically improve after shunt revision surgery.

10.6 Shunt Failure

10.6.1 Epidemiology of Malfunction

Articles on shunt malfunction report a remarkably consistent failure rate of 30 to 40% within the first year. In 1994, Di Rocco et al published the results of a cooperative survey of ISPN members.⁴ Thirty-eight neurosurgical centers submitted data on 773 patients. Two hundred twenty patients (29%) required a shunt reoperation in the first year. Although a univariate analysis of risk factors for shunt failure was performed with data gathered over a vague time period, the findings were as follows: (1) of shunts inserted at emergency surgery, 34% failed, compared with 29% of shunts inserted electively; (2) failure rates were the same for surgeons and residents; (3) unconscious patients had a 40% failure rate, compared with a failure rate of 30% in those whose consciousness was not impaired; (4) distal shunt insertion by open laparotomy had a 32% failure rate, compared with a 24% failure rate when a trocar was used; (5) the infection rates were 6.7% for patients who received prophylactic antibiotics and 4.5% for patients who did not receive prophylactic antibiotics; and (6) the failure rate for shunts inserted in the first 6 months of life (35 to 47%) appeared to be substantially higher than that for children older than 6 months (14%).

In a detailed review of an extensive experience, Piatt and Carlson reported on 727 shunt operations over a 13-year period.⁴⁶ Among the 671 simple linear shunts, the failure rate was 32% at 1 year. Simple shunts had better survival than complex shunts. Age was a significant risk factor for failure, with children younger than 2 years at higher risk than older children. Another interesting finding was that revision of a shunt after a short interval (less than 6 months) resulted in a risk for failure higher than that of new shunts or shunts revised after a longer interval. The cause of the hydrocephalus, duration of the operation, time of day of the surgery, and presence or absence of epilepsy did not have a significant effect on the risk for shunt failure. The conclusion was that factors under the control of the surgeon seemed to influence shunt survival to a lesser degree than factors intrinsic to the patient.

In their review of 1,719 patients, Sainte-Rose and colleagues found a shunt failure rate of 30% in the first year (deaths and infections were excluded).²⁵ They emphasized that different types of failure occurred at different times. For example, shunt fracture or disconnection tended to occur late, as did the need for elective lengthening of a shortened catheter. As previously mentioned, when univariate analysis techniques were used, the findings suggested a lower failure

rate with a posterior tip position than with a frontal ventricular catheter tip position, and a decreased failure rate for proximal compared with distal slit valves.

10.6.2 Types of Failure

Obstruction

Obstruction to flow can occur at any point along the shunt system; however, it most commonly occurs at the ventricular catheter. Obstruction of the ventricular catheter is probably the most common mechanical complication of shunts, accounting for 63.2% of mechanical complications.⁴ When the type of shunt failure was examined over time, proximal obstructions and infections were more common early after insertion; distal obstructions and disconnections were more common in late failures.⁶²

Although overdrainage is often discussed separately from obstruction of the ventricular catheter, the two may be related. If the drainage of the ventricular system is slow enough to keep the ventricles distended a little bit, the chance of the ventricular catheter adhering to the wall or becoming embedded in the choroid plexus may be lower. This notion is supported by a review of the data from Sainte-Rose et al, in which the rate of mechanical complications was 44.3% in cases of slit ventricles, compared with rates of mechanical complication of 27.1% and 36.1% when the ventricles were normal or enlarged, respectively.²⁵

Obstruction of the valve is much less common and usually occurs very early after shunt insertion or proximal shunt revision. Presumably, valve obstruction is due to cellular debris or blood that gets into the ventricular catheter, passes into the valve, and obstructs the valve.

Disconnection and Migration

Although rare, it is possible for the components of a shunt system to disconnect or for the whole system to move distally so that the ventricular catheter slides out of the ventricular system. These complications tend to occur early after shunt surgery, and they are easily detected on plain radiographs.

Fracture

Fracturing of shunt tubing is almost always a late complication.⁶² It is usually observed in tubing that has been in place for a long time, has become calcified, and has subsequently cracked. Commonly, the patient's shunt will function for a while after the fracture because CSF will pass through the fibrous sheath that usually surrounds the shunt tubing. Eventually, though, CSF flow fails and the patient presents with shunt malfunction.⁶³ Shunt tubing fractures are usually discernible on plain radiographs (► Fig. 10.12a). Fractured tubing most commonly occurs in the neck.^{63,64} In one large series, fractures were observed in 60 of 2,065 shunt procedures (3%).⁶⁵

Overdrainage

Shunt overdrainage either may be seen as extra-axial fluid collections or may be classified as SVS.

Extra-axial Fluid Collections

With the collapse of the ventricular system, extra-axial fluid and/or blood can accumulate (► Fig. 10.12). This was observed in 12 of the 344 patients (3.4%) in the randomized SDT.⁵ Extra-axial fluid collections usually occur in an older child with large ventricles early after insertion of a new shunt. Management of these collections can be very difficult; two primary approaches have been used: (1) decreasing or stopping the overdrainage, usually by changing the shunt valve to one with more resistance or to one with a siphon-resisting device; (2) draining the extra-axial fluid. The second approach may be accomplished by creating a bur hole and placing a temporary drain or by inserting a subdural catheter and connecting it to the existing shunt system below the valve. This latter option results in drainage of the extra-axial fluid with little or no resistance. The intraventricular catheter still has the resistance of the valve, and therefore there is a relative pressure gradient from the ventricular system out to the extra-axial fluid space, which results in brain expansion as the extracerebral fluid drains. The best treatment for this type of overdrainage, however, is to avoid it, and caution should be exercised in placing a shunt in the older child with large ventricles.

We have occasionally used programmable valves in high-risk patients. We tend to begin with the valve pressure set toward the higher end (e.g., Codman-Medos at 150, Strata at 2.0) and then gradually reduce the valve pressure over many months. Furthermore, in children who develop extra-axial collections, we have temporarily raised the valve to the highest setting and seen these collections resolve on follow-up imaging studies (► Fig. 10.6).

Slit-Ventricle Syndrome

There are children in whom very small ventricles develop in a delayed fashion after shunt insertion, and some of them are labeled as having SVS. A consistent definition of the syndrome is lacking in the literature. Perhaps a more convenient term would be *symptomatic small ventricles*. Nevertheless, the term *slit ventricle syndrome* is in such common use in pediatric neurosurgery that it is unlikely to change.

Affected patients have usually had a shunt in place for at least several years, and their ventricles have become very small over time (► Fig. 10.12e). In addition, they have symptoms similar to those of shunt malfunction. Their most common complaint is headache. Typically, the symptoms are repetitive or cyclical in nature and consist of intermittent headaches, nausea or vomiting, and other signs consistent with elevated ICP. The symptoms are often related to posture; patients may report improvement after a period of recumbency.⁶⁶ An acute presentation is also possible, with lethargy and coma.^{67,68}

In a retrospective review at Primary Children's Medical Center, it was noted that slit ventricles occurred in 270 of 370 patients (64%).⁶⁶ Only 18 patients (6.5%), however, had symptoms severe enough to warrant surgical management. In the ISPN survey, excessive drainage was observed in fewer than 1% of all patients with newly implanted shunts.⁴ SVS was not observed in any of the 344 patients in SDT (follow-up, 1 to 3 years).⁵ An incidence of 1.8% was observed in a series of 120 patients with ventriculoatrial shunts.⁵⁵

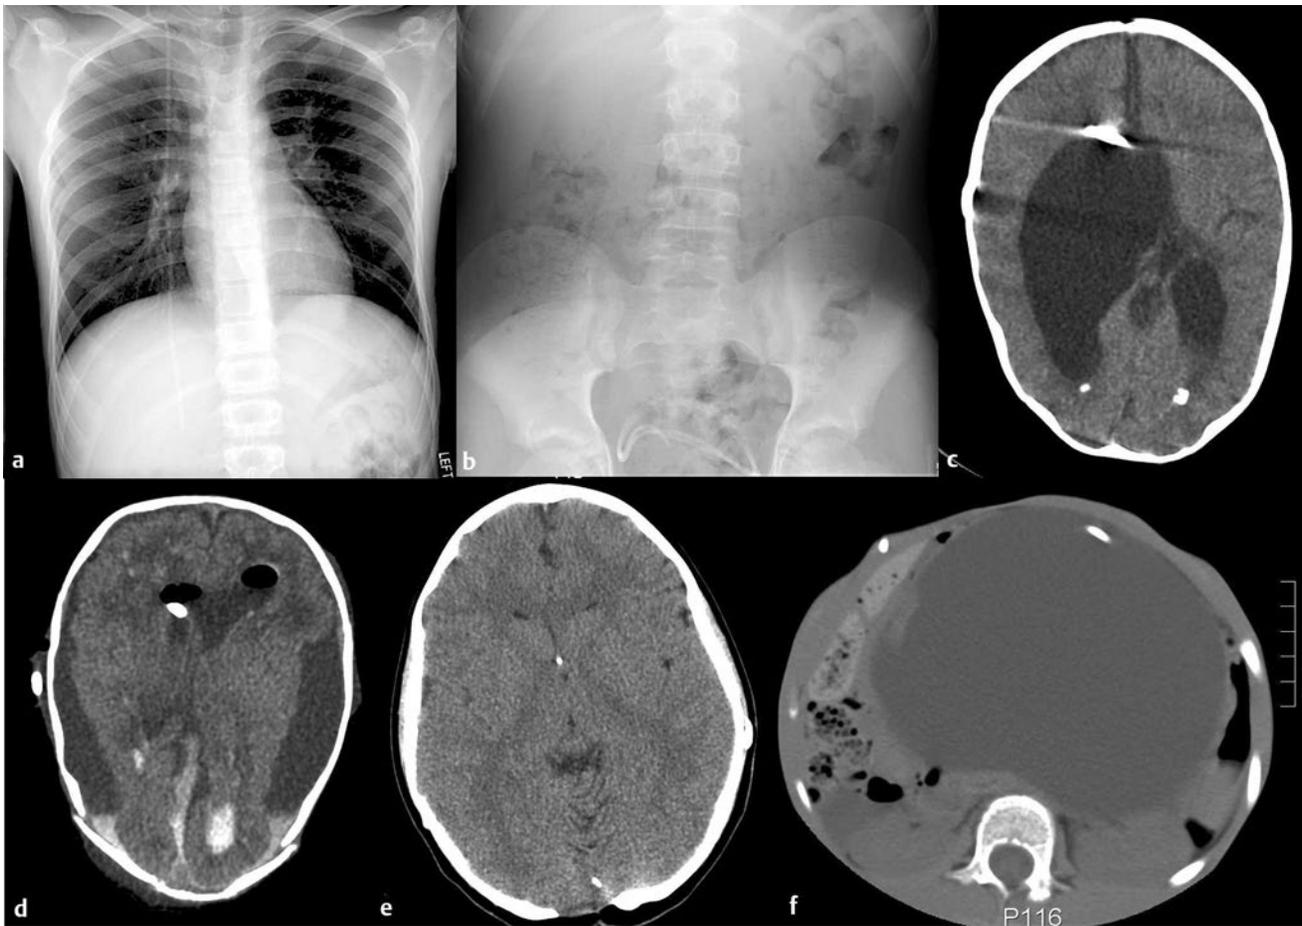

Fig. 10.12 Numerous types of shunt complications can occur, (a,b) including shunt fracture, (c) loculate CSF collections, (d) overdrenage leading to subdural collections or (e) slit ventricles, and (f) abdominal pseudocysts.

This syndrome presents quite late after shunt insertion, and its incidence may increase with longer follow-up. One study reported a mean time of 6.5 years to the development of a clinical picture.⁶⁹ When long-term follow-up (16 years) was obtained for 70 patients with shunts, Sgouros et al found a 10% incidence of SVS requiring surgery.⁷⁰

Pathophysiology

Although several pathophysiologic mechanisms have been proposed for SVS, none has received unequivocal scientific support. One hypothesis is that an implanted shunt system overdrenes CSF from the ventricular system because of the siphoning effect of the distal catheter. The siphoning is due either to the gravitational force of the column of fluid in the distal shunt tubing or, in the case of atrial or pleural shunts, to negative pressure environments at the distal tip of the shunt.

Overdrenage over the long term results in small ventricles and allows the brain to completely fill the intracranial space. As a result, the ability to compensate for transient changes in intracranial volume is impaired. In addition, the small ventricles cause intermittent ventricular catheter obstruction. This obstruction may be symptomatic without much (or any) change in ventricle size because of the brain's poor compensatory mechanisms. The underlying pathophysiology may also account

for the occasional incidence of sudden death in patients with shunts who have been found to have normal ventricles at autopsy.

Management

Although only a small percentage of children with shunts will develop SVS, the management is complex; they often account for a disproportionate number of shunt-related consultations and procedures. Conservative approaches that are appropriate in many cases include observation and medical therapy. In a review by Walker et al,⁶⁶ 13 (42%) of the 31 patients with the clinical diagnosis of SVS were managed successfully without surgical intervention. This approach is reasonable if a child's symptoms are infrequent and do not prevent participation in daily activities. Antimigraine therapy has appeared as an alternative first step in several articles and reviews.^{66,71,72} Whether the observation that some children with SVS improve on such therapy is a reflection of misdiagnosis or of efficacious therapy is not answerable at present. It has been argued that the child with SVS has such poor brain compliance that any factor that increases intracranial volume is highly likely to precipitate symptoms. In the case of antimigraine therapy, stabilization of the cerebral blood flow may minimize the intracranial volume changes and lead to symptomatic relief.

If conservative measures are not sufficient, several surgical approaches have been described.^{66,73} In some situations, ICP monitoring may be helpful. Low pressure during symptoms may respond to upgrading the existing valve, adding a siphon-resisting component, changing to a flow-control valve, or changing the setting of an adjustable valve. The management of patients with high pressure during symptoms is more problematic. Although cranial expansion and subtemporal decompression have been advocated in the past, shunt revision is now preferred. Revising the ventricular catheter in such patients can be difficult, and the surgeon runs the risk of not being successful at placing the new catheter. Several technical options have been suggested: (1) dilating the ventricular system under close observation and ICP monitoring, followed by reinsertion of the ventricular catheter; (2) using endoscopy, fluoroscopy, or stereotaxis during the revision; and (3) performing an endoscopic third ventriculostomy.^{74,75} Despite these maneuvers, managing such patients remains one of the most difficult and frustrating tasks in pediatric neurosurgery.

Loculation

Shunted ventricles are often asymmetric, with the lateral ventricle on the side of the shunt somewhat smaller than the one on the other side. Such asymmetry is usually mild, and the patient is asymptomatic. Occasionally, however, a shunt will drain only a portion of the ventricular system, leaving another area enlarged and causing mass effect (► Fig. 10.12c). Referred to as loculation, this scenario is very common in patients who have had ventriculitis or whose ventricles are loculate preoperatively. Although less common, it may be found in others as well. Isolation of a lateral ventricle has been described in a series of 8 patients without infection who presented 3 weeks to 7.5 years after shunt insertion. Two of them had IVH, and 6 patients were myelodysplastic. The proposed mechanism was overdrainage of the ipsilateral ventricle, resulting in functional obstruction of the foramen of Monro and a dilated contralateral ventricle.⁷⁶ When the experience at Primary Children's Medical Center was retrospectively reviewed, 43 septostomies were performed in 32 patients with an isolated lateral ventricle over an 8-year period. At a mean follow-up of 31 months, 81% of children had relief of their isolated lateral ventricle, with no septostomies failing at 6 months postoperatively. A prior history of multiple shunt procedures was highly predictive of initial septostomy failure, increasing this risk by 4.5.⁴⁷

Symptomatic children with an isolated fourth ventricle need to be treated. Sudden deterioration with cardiorespiratory arrest and death has been reported in one patient in a series of 10 who had an isolated fourth ventricle.⁷⁷ Of the 10 patients in the series, 9 presented with irritability and headaches, and 4 of 6 infants had opisthotonos. Imaging showed small or slitlike lateral ventricles; a large, rounded fourth ventricle; ventral displacement of the brainstem; and loss of the posterior fossa subarachnoid spaces. Treatment consisted of a fourth ventricle catheter that was added to the existing shunt, above the valve.

Infection

See Chapter 71 for a detailed discussion of shunt infections.

Mortality

Sainte-Rose et al observed a 1.05% mortality rate directly related to shunt failure in 1,719 patients over a 10-year period,²⁵ but a much higher mortality rate of 12.4% at 10 years was reported in a series of 907 patients.⁷⁸ The only risk factor for death was a history of shunt infection.

10.7 Follow-up of Patients after Shunt Insertion

After shunt insertion or revision, patients are usually reassessed within the first 2 or 3 months and then annually. The need for imaging studies at follow-up visits was investigated by Steinbok et al.⁷⁹ They retrospectively reviewed 86 children who had follow-up imaging studies. Of the 6 children whose first follow-up study was done beyond 3 months postoperatively, none had further change on subsequent imaging studies. The other 80 patients had studies before 3 months, and 39 (49%) of them had a further decrease in ventricle size on later images. Of the 14 patients who underwent imaging studies in the first 3 weeks after surgery, 10 (71%) showed further change on later studies. The authors concluded that a study done at 3 months postoperatively would be an adequate baseline for subsequent follow-up. Further information on this issue was obtained from SDT, in which all patients had a study between 2 and 4 months postoperatively; most patients also had a study at 1 and 2 years. The ventricle size was measured by a modified Evans ratio. Although the ventricle size at each time point had a wide range, it appeared that in most cases, there was a further decrease in the size of the ventricles at 1 year compared with 3 months. At 2 years, however, there was no further decrease in the size of ventricles.⁵

At Primary Children's Medical Center, we immediately obtain CT scans postoperatively and again at 3 and 12 months. Although the ventricles may continue to get smaller, the immediate and 3-month scans are still worthwhile because shunt failure is so common in the first year. If the shunt is still functioning at the end of the year, a 12-month image will provide a better baseline for long-term follow-up.

The other consideration is the type of follow-up study. In general, CT is used, and babies who start out with ultrasound are converted to CT when their fontanel closes.

10.8 Shunt Revision

VP shunt revision is probably the most common operation done by pediatric neurosurgeons. At the time of shunt revision, preoperative preparation and positioning should allow access to the whole shunt system because it is often difficult to predict the location of the malfunction. It is also important for the surgeon to be aware of the shunt system that the patient has in place so that the appropriate replacement needs is facilitated. In addition, the surgeon needs to be familiar with the different flow characteristics of different shunt systems in order to interpret the shunt function intraoperatively.

At Primary Children's Medical Center, our preference is to begin by opening the cranial wound, separating the ventricu-

lar catheter above the valve, and assessing the spontaneous flow (or lack thereof) out of the ventricle. Distal runoff through the valve and peritoneal catheter is also assessed with manometry. Interpretation of the latter maneuver requires knowledge of the valve in place and its usual expected flow characteristics. If poor runoff is obtained, it is important to then remove the valve and test the peritoneal catheter by itself to detect blockage within the valve. For patients with good runoff but poor flow from the ventricular catheter, the first maneuver is to remove the old ventricular catheter. The ventricular catheter is commonly stuck, and its removal with a Bugbee wire (Olympus Global, Center Valley, PA) can be very effective.⁸⁰ The Bugbee wire should be passed into the ventricular catheter with care so that it is not advanced beyond the tip of the catheter into the brain. The coagulating and/or the cutting current may be used to free the adhesions within the ventricular catheter. The catheter is then gently withdrawn, and a new one is passed.

Endoscopes are now available that will fit down the ventricular catheter during shunt revision surgery. The goal in such cases is to place the new catheter in a position away from the site where the old catheter was stuck. As previously mentioned, although ESIT did not demonstrate improved shunt survival with first-time shunts, the endoscope may occasionally be helpful in situations of complex ventricular anatomy to confirm catheter placement within the ventricular system.

If a valve is being replaced, it is most commonly replaced with one having the same flow characteristics unless the preoperative decision was to change the valve characteristics. This is usually not the case for shunt obstruction but may be appropriate in suspected overdrainage.

When there is a distal blockage, the whole peritoneal catheter should be replaced from the valve down to the abdomen. Cutting across the peritoneal tubing at the abdominal scar and attaching a new piece of tubing at that point with a straight connector results in fixation of the shunt at this point and predisposes to subsequent disconnection or fracture.

The peritoneal catheter may be replaced by using the tunneler for shunt insertion, or it can be pulled through the same tract by using the old peritoneal catheter or a guidewire.

10.9 Complications

Acute complications from insertion of the proximal catheter include hemorrhage and neurologic injury. Intraparenchymal hemorrhage related to shunt surgery occurs in approximately 1% of cases and is more common if the old ventricular catheter is removed.⁵⁰ Hemiparesis is possible if the catheter traverses the internal capsule, but in most cases this deficit is transient.

Abdominal visceral or vascular injury can occur after placement of a peritoneal shunt. Perforation of viscera can occur either at the time of shunt insertion or later from erosion of the tubing through the visceral wall.^{50,81,82} Perforations of the stomach, small and large bowel, bladder, and uterus have been reported.⁸³ Delayed erosion of catheters through bowel walls are thought to be more common with catheters reinforced with springs.⁸⁴

Pseudocysts are loculate pockets filled with unabsorbed CSF (► Fig. 10.12f). The cyst wall is a peritoneal serous membrane

thickened by chronic inflammatory tissue rather than by formed mesothelial tissue; thus, it is a pseudocyst. A low-grade shunt infection with *Staphylococcus epidermidis* or *Propionibacterium acnes* has been identified as the causative factor in 30 to 100% of pseudocysts, with most series reporting a rate of at least 60%.^{85,86} In addition to infection, multiple previous abdominal operations and chronically elevated levels of CSF protein have been identified as risk factors for the formation of pseudocysts.⁵⁰ Pseudocysts usually occur in a delayed fashion, even up to years after the last shunt operation, and can cause abdominal pain, distention, vomiting, fever, or poor appetite. The vast majority of patients with pseudocysts do not show symptoms of shunt malfunction.^{85–87} Treatment of the pseudocyst requires removal of the peritoneal catheter, at which time fluid from the pseudocyst can be aspirated in a retrograde manner through the catheter and the CSF and tip cultured. The pseudocyst typically subsides after the peritoneal catheter is removed; a laparotomy is rarely required. Given the high incidence of infection, at Primary Children's Medical Center we prefer to start antibiotic therapy immediately and continue it until CSF cultures are negative for 5 days. At that point, we typically convert the peritoneal shunt to an atrial or pleural shunt.

With pleural shunts, pulmonary parenchymal injury, pneumothorax, and effusion are the most common complications.⁵⁰ Most of these complications can be managed with observation alone. If pleural effusions become large and symptomatic, serial thoracentesis or removal of the distal catheter may be necessary. Distal components of ventriculoatrial shunts can cause thrombosis around the tip, with or without pulmonary embolus. This complication has been reported in up to 40% of patients with atrial shunts.^{88,89}

Craniosynostosis is a rare complication of CSF shunting that occurs only in patients who had a shunt placed before 6 months of age. Surgery is warranted if the child is developing well and the alterations in the cranial vault are cosmetically significant or if there is evidence of raised ICP in the presence of a working shunt. In such cases, cranial vault reconstruction may be necessary.⁵⁰

10.10 Shunt Removal

One of the most common questions asked by parents whose child is having a shunt placed for the first time is whether the shunt can be removed later. Another relatively common scenario is that of an older patient who returns for follow-up, apparently clinically well, with a disconnected shunt seen on radiographic examination, which might suggest that removal of the shunt is possible.

Whittle et al studied 46 children with arrested hydrocephalus.¹⁰ Thirty of these children had had shunts placed previously but appeared to be shunt-independent at the time of the review. The diagnosis of shunt independence meant that (1) the shunt had been clipped or removed or (2) an isotope shunt study had confirmed shunt blockage and serial neuroradiographic studies had confirmed that the hydrocephalus was not progressing. All of these patients underwent ICP monitoring, and 24 (80%) of the 30 patients with apparent shunt independence demonstrated intermittent or persistent intracranial hypertension. ICP tracings were normal in 6 (20%) of the 30 patients. On the basis of the results of the ICP recordings, all 24

patients had their shunt re-established, but clinical follow-up was not reported.

True shunt independence in children who have had shunts in place is uncommon; thus, great caution should be exercised in concluding that a child's shunt does not need to be fixed. Long-term vigilance with a very low threshold for re-evaluation is warranted because late deterioration after a period of apparent compensation and/or shunt independence has been documented.⁹⁰

10.11 Late Outcome after Shunt Placement

Late outcome after shunt placement depends in part on the cause of the hydrocephalus. Sgouros et al reviewed 70 patients who had shunts inserted between 1974 and 1978 and were followed for a minimum of 16 years.⁷⁰ Patients who died before the age of 16 years or who had tumors or posttraumatic hydrocephalus were excluded. The average age at follow-up was 19.1 years; the average age at shunt insertion had been 5.1 months (all 2 years of age or younger). Of the 201 shunt-related operations, 33 (16%) were performed on the children after the age of 16 years (26 shunt malfunctions and 7 infections). Of the children with myelomeningocele, 35 (50%) attended regular schools and 28 (40%) were in special school settings for the physically handicapped; 7 (10%) had mental handicaps that prevented normal education. Patients with meningitis and IVH had the worst outcomes, with mental handicap rates of 30% and 40%, respectively. Two-thirds of all patients were socially independent but living with parents (age-related), 12 children (17%) were dependent, and the remaining patients were either independent or married. Of the whole population, 10 children (14%) were either unemployable or required specially structured work environments. In this study, there were two late deaths and four major complications related to shunt malfunction and infection.

10.12 Issues in the Older Child and Adult

As the population of children with shunts ages, some issues relevant to young adults have appeared in the literature. Rekaté recommended that children who have large ventricles avoid contact sports.⁹¹ In addition, he suggested that young adults who have experienced coma when their shunts malfunctioned establish an outside contact system to ensure their well-being if they are living alone. The literature on managing shunts during pregnancy has shown that the presence of a shunt is not a contraindication to pregnancy; labor and delivery should be allowed to progress naturally.^{92,93} Interventions should be based on obstetric indications. Symptoms of shunt malfunction are common in pregnancy, but they resolve with delivery. Shunt pumping usually provides symptomatic relief in the interim.

10.13 Editorial Comment

The authors describe the multitude of factors that should be considered in making the decision about whether to insert a

shunt, a decision that is probably of more importance than the insertion site or shunt type. Kestle, Drake, and others who have conducted randomized clinical trials have increased our knowledge about shunting significantly.^{5,6} Technologically, we need methods to place ventricular catheters in the desired positions and to noninvasively measure ICP in patients with shunts, as well as methods to assess shunts that do not siphon.

Pearls

- Repeated assessments over time may be necessary to demonstrate progressive hydrocephalus that requires a shunt. In difficult cases, ICP monitoring may be helpful.
- When choosing shunt equipment, the surgeon should become familiar with one system and use it consistently.
- After shunt insertion, baseline images should be obtained immediately postoperatively and at 3 and 12 months. The decision not to fix a child's disconnected shunt should be made with great caution.
- Although endoscopically assisted placement of ventricular catheters has not been shown to extend the longevity of first-time shunts, it can be very helpful in shunt revisions to confirm catheter placement in the ventricular system.
- Placing the ventricular catheter tip away from the choroid plexus may reduce the chance of proximal shunt obstruction.

11 Neuroendoscopy

Alan Cohen and Timothy W. Vogel

The field of neuroendoscopy has undergone an evolution in the past several decades, with increased attention given to minimally invasive approaches to various intracranial and spinal pathologies. With improved instrumentation, neurodiagnostic imaging, and surgical experience, pediatric neurosurgeons are now aware of the benefits and limitations of neuroendoscopy. Accompanying the improvement in surgical techniques and equipment is an ever-expanding base of scientific literature to help define patient selection, determine surgical outcomes, and describe potential complications and their management. Recent publications utilizing neuroendoscopic procedures have grown exponentially in the last decade and continue to expand in their diverse central nervous system (CNS) applications. Neuroendoscopy has been transformed as a field and is now part of a pediatric neurosurgeon's armamentarium, with neuroendoscopy incorporated into cerebrospinal fluid (CSF) diversion, tumor resections, intracranial cyst fenestrations, skull base approaches, and spinal surgeries. There is also a growing role for endoscopically assisted microneurosurgery in these aforementioned surgeries.

This chapter focuses primarily on intracranial approaches with neuroendoscopy, and there is some mention of its use in spinal surgery. The current instruments frequently employed in endoscopic approaches are discussed, as well as the orienting anatomy that is identified throughout the neuroendoscopic procedures. The current applications of endoscopy are also described, along with surgical decision making regarding the limitations of endoscopy. Finally, potential complications arising during surgery and strategies for their management are discussed.

11.1 History

The roots of neuroendoscopy actually begin within the field of urology. Victor Darwin Lespinasse, a urologist in Chicago, utilized a rigid cystoscope to fulgurate the choroid plexus in two infants with hydrocephalus. Walter Dandy, considered to be the father of neuroendoscopy, began utilizing this technique to extirpate the choroid plexus in cases of congenital hydrocephalus.¹ During his procedures, Dandy initially used a small nasal speculum to gain access to the posterior horns of the lateral ventricles and drain the CSF for access to the choroid plexus. Later, Dandy developed long-handled surgical instruments to accompany electrocautery in his endoscopic transventricular surgeries. Dandy developed an open form of third ventriculostomy for the diversion of CSF. The first endoscopic third ventriculostomy (ETV), however, was performed by W. Jason Mixer.² He developed the procedure in the cadaver of a child with hydrocephalus and translated his approach to patients. Around this time, in 1923, endoscopic photography was developed at the University of Pennsylvania by Fay and Grant, who captured the first endoscopic images of the choroid plexus.^{2,3}

These early innovations paved the way for more advanced optics and instrumentation, which were subsequently developed for cauterizing the choroid plexus in infants with hydro-

cephalus. Scarff at the Neurological Institute of New York at the Columbia University College of Physicians and Surgeons pioneered angled lenses⁴ to improve the field of view and utilized a monopolar electrode that could be advanced and retracted in a working channel of the endoscopic sheath.⁵ Scarff was able to irrigate the field and perform surgery at a fluid-filled interface, a technique that had been developed earlier by Putnam¹ to improve the primitive optics available at the time.⁶ Despite these adaptations, neuroendoscopy had a limited role in the treatment of hydrocephalus and was hindered by the considerable morbidity and mortality associated with these cases.⁷ With the introduction of the valved ventricular shunt in 1949 to treat hydrocephalus, the use of endoscopy declined.⁸

Unexpectedly, the same development that helped endoscopy fade from mainstream neurosurgery also helped it return to a critical role in pediatric neurosurgery.⁹ The complications of infections and shunt malfunctions associated with CSF shunt systems remain a persistent source of morbidity and mortality in children, and in an effort to reduce the shunt burden in children, neuroendoscopy¹⁰⁻¹³ has seen a resurgence in its use in the past two decades.⁷ In addition, instrumentation and optics have improved significantly and are now tailored to intracranial applications. With renewed interest, neurosurgeons employing neuroendoscopy¹⁴ are now exploring the boundaries of minimally invasive applications in various neurosurgical settings.

11.2 Instruments

11.2.1 Flexible and Rigid Endoscopes

The selection of endoscopes is critical for determining the types of surgical procedures that pediatric neurosurgeons undertake. The selection of available endoscopes is more diverse than the early cystoscopes, and innovation has been largely driven by technological improvements in digital imaging, optics, and minimally invasive surgical techniques. The types of endoscopes available can be generally classified as rigid and flexible, each having its advantages and disadvantages. Rigid endoscopes have traditionally had superior optics, relying on the segmental optics first pioneered by Harold Hopkins,^{15,16} an English physicist, and the optics are now coupled to a high-intensity light source, such as xenon. The rigid endoscope is introduced through a rigid sheath that can be equipped with several working channels to facilitate the introduction of microsurgical instrumentation as well as the ingress and egress of CSF and saline to flush debris and improve visualization. Adding these channels allows a fluid interface to be maintained throughout the surgery and ensures that the intracranial pressure (ICP) is kept at an atmospheric level, thereby preventing the accumulation of intracranial fluid and the resulting increase in ICP. Rigid endoscopes¹⁷ can also be outfitted with various angled lenses to widen the field of view around certain structures. Care must be taken when changing these lenses and steering through the ventricles and intracranial contents as orientation can be changed depending upon the lens angle selected.¹⁸

Additionally, rigid endoscopes and their sheaths are now available in a variety of sizes to accommodate neonatal pathologies.¹⁹

Rigid endoscopes, however, lack the maneuverability of their flexible counterparts. Flexible endoscopes can be used to peer around structures²⁰ with little movement at the cranial surface or translational movement through the cortex. Flexible endoscopes utilize fiberoptic technology to permit maneuverability, but this currently limits the amount of transmitted light. Flexible endoscopes²¹ require a different steering technique from rigid endoscopes to ensure that anatomical orientation²² is preserved throughout the procedure so as not to damage adjacent neural structures. Takanori Fukushima^{23,24} in Tokyo, Japan, is credited with pioneering the use of the flexible endoscope, primarily for biopsies of intraventricular lesions.¹⁵ Flexible endoscopes can now be used together with rigid endoscopes²⁵ in a scope-within-scope setup²⁶ in which the neurosurgeon can capitalize on the benefits of each scope.²⁷

11.2.2 Endoscope Holders; Digital and Three-Dimensional Imaging

A frequently overlooked aspect of neuroendoscopy is that a team,²⁸ in which an additional surgeon or a trained assistant is needed to manipulate the scope with an extra set of hands, often performs the surgery. It is advantageous to have one surgeon hold and manipulate the endoscope while another works with the instruments. To support the endoscopes and minimize translational movement through the exposed cortical surface, endoscopic holding arms have been invented that allow the operating surgeon to work alone (► Fig. 11.1). Pneumatically operated arms^{29,30} can be sterilely draped in the operative field and fixed in a locale that allows delicate microsurgical manipulation with a decreased risk for awkward movements or inadvertent changes in depth or direction throughout a procedure.³¹ In addition to rigid fixation of the endoscope, recent technology has made possible three-dimensional neuroendoscopy,² and improved digital imaging has become available and is moving two-dimensional images closer toward those seen during open microsurgery.³² Digital imaging ensures high-quality reproduction of the represented anatomy for the surgical team, and the

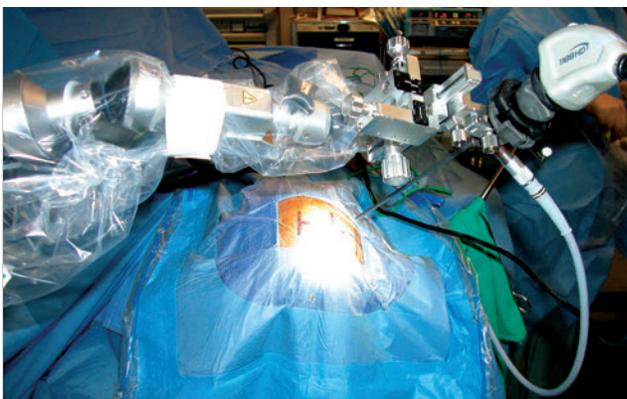

Fig. 11.1 Intraoperative picture of a pneumatic endoscope holder that has been sterilely draped and utilized to hold the neuroendoscope.

addition of three-dimensional imaging allows an improved appreciation of the relationships between neural structures. Three-dimensional imaging relies on two parallel cameras in the endoscope to display the digital images for three-dimensional reproduction.³¹ Regardless of the dimensionality used, digital images and movies allow better patient education regarding planned surgery and surgeon training in preparation for the encountered anatomy.

11.2.3 Surgical Instruments and Lasers

To accompany the scopes and digital imaging, surgeons have designed microinstruments³³ to facilitate dexterity during neuroendoscopic procedures.²⁶ These instruments are introduced through the working channels of the sheath and are separate from the irrigation ports for CSF and saline ingress and egress. The tools available to the neuroendoscopist continue to expand yearly, and they are designed for grasping, cutting, and sampling tissue.⁶ Rigid and flexible probes allow penetration through cyst walls,³⁴ whereas balloon catheters³⁵ allow the controlled dilation of openings made for ETVs,^{36,37} cyst fenestrations,^{38,39} septostomies,⁴⁰ and aqueductoplasties.^{20,21,41} Electrocautery with monopolar^{42,43} or bipolar current facilitates hemostasis and makes possible the manipulation of vascularized tissues, such as tumors, cyst walls, and choroid plexus.^{29,44} Multiple working channels on the sheath facilitate the use of two instruments concurrently to manipulate tissue.

Endoscopes may be outfitted with lasers⁴⁵ to permit cutting through tissues. The lasers most commonly utilized in neuroendoscopy are the neodymium-doped yttrium–aluminum–garnet (Nd:YAG) laser, the argon laser, and the potassium titanyl phosphate (KTP) laser.^{4,6,46} The Nd:YAG laser emits light with a wavelength of 1.064 μm , which is in the near-infrared spectrum, and the light is aimed with a visible helium–neon pilot beam. Nd:YAG lasers are used to cut or coagulate pigmented tissues, as laser absorption is preferential in these tissues.⁴⁷ KTP lasers⁴⁸ emit light with a wavelength of 0.532 μm , which is within the visible spectrum.⁴⁹ This laser can be used for dissecting because less thermal injury is produced.²

11.2.4 Stereotactic Endoscopy

Stereotactic navigation⁵⁰ and intraoperative real-time anatomical localization continue to improve neuroendoscopic surgeries. Preoperative high-resolution magnetic resonance (MR) imaging and computed tomography (CT) can be fused to allow pediatric neurosurgeons to plan surgical approaches and identify critical vascular structures that might otherwise limit their resections or exposures.⁵¹ During endoscopic surgery, there is always the potential for disorientation and potential injury to uninvolved anatomical structures. Multiloculate hydrocephalus^{52,53} requiring multiple cyst fenestrations for the communication of fluid spaces is a condition in which intracranial structures are difficult to differentiate from one another. Stereotactic localization^{54,55} helps orient the surgeon to the proper cyst wall and potential underlying structures. In addition, in transnasal surgeries,⁵⁶ preoperative CT of the skull base and maxillofacial region allow intraoperative midline orientation^{57,58} during attempts to identify the floor of the sella turcica and differentiate between anatomical variants with septate bone. Midline cranial

approaches, such as transcallosal^{59,60} surgery, may also benefit from stereotactic preoperative localization, in which venous lakes that communicate with the superior sagittal sinus are identified and intracranial entry can be planned away from these large cortex-draining venous structures.^{61,62} In addition, pediatric neurosurgeons, in an effort to reduce the amount of cortical injury in children, can plan approaches to minimize the length of the endoscopic trajectories used to reach a targeted region.

Intraoperative fluoroscopy^{30,63} and ultrasound may also be used if guidance systems are not available or become dysfunctional during surgery. In children with open fontanels, ultrasound^{53,64,65} over the anterior fontanel can be used to visualize the endoscope in relation to the underlying pathology.⁶⁶ One potential limitation of neuronavigation is brain shift and the collapse of fluid cysts or other fluid spaces once the endoscope has been introduced. Surgeons must be careful to correct for these changes during endoscopic procedures. Like all technology, stereotactic localization must be coupled with a working knowledge of anatomy to ensure that the information being displayed fits the anatomical endoscopic picture.

11.3 Endoscopic Anatomy

The following section focuses primarily on the intracranial anatomy encountered during transventricular approaches with the endoscope.^{20,67,68} There are key structures that need to be identified when the endoscope is introduced into the ventricles, and they serve as beacons throughout the case, reminding the surgeon of adjacent neural and vascular structures. Caution must be taken, however, as the normal anatomy may be obscured or distorted by the pathology of interest. If this occurs, neuronavigation with stereotactic localization may be utilized to verify the anatomy. In general, cranial endoscopy is safest if performed in the presence of ventriculomegaly, which allows the surgeon adequate visualization of the anatomical structures and room to maneuver the endoscope. If small ventricles are present, stereotactic localization may aid in cannulation of the ventricles.^{69,70} Before cannulation, proper scope orientation must be verified to ensure that the lens is not mistakenly inverted from a desired orientation.⁶³ This allows proper orientation throughout the case and prevents the inadvertent manipulation of tissue. In addition, when a transventricular approach to a lesion is used, a small needle with a stylet may be introduced into the cortex and ventricle to ensure that the planned trajectory and orientation traverse the ventricle.⁷¹ With the stylet⁷² removed and CSF appreciated, the endoscope can then be introduced along the trajectory of the needle as it is removed.

In general, the structures viewed with an endoscope look different from those visualized with a stereoscopic operating microscope.⁷³ The location of structures is relatively constant intracranially, but care must be taken for structures that lie outside the limited field of view while the endoscope is maneuvered. This becomes particularly important in depth perception, in which other signals, such as brightness, shadowing, and response to infusion of saline, will help the surgeon determine a structure and estimate its depth.²

The first structure that the endoscope encounters after penetrating the cortical surface and ventricular walls is often the floor of the lateral ventricle, which has a smooth, white ependymal surface. Here, the frondlike vascularized choroid plexus can be appreciated, lying in the choroidal fissure and leading anteriorly to the medial floor of the lateral ventricle. The choroid plexus then dives into the foramen of Monro and covers the roof the third ventricle posteriorly.^{67,74} The foramen of Monro serves as a landmark for endoscopists as it often guides surgeons to the proper location for an ETV or to the inspection of third ventricular lesions or the cerebral aqueduct (► Fig. 11.2). The foramen of Monro may be obscured, however, by intraventricular pathology, such as tumors, infections, or cysts. Identifying the choroid plexus overlying the thalamus in the choroidal fissure and leading to the foramen of Monro can help verify its location. An additional landmark that may be seen medially is the septum pellucidum, which may be patent or intact depending on the particular case. The head of the caudate nucleus may be seen lateral to the foramen of Monro. Neurovascular structures also serve as a roadmap intraventricularly, where the thalamostriate vein, coursing alongside the choroid plexus, joins the anterior septal vein at the foramen of Monro to form the internal cerebral vein.

Structures surrounding the foramen of Monro include the c-shaped fornices arching over the foramen. These fiber bundles contain efferent projections from the hippocampus and subiculum and define the anterior and medial borders of the foramen of Monro. The fibers terminate in the mammillary bodies on the floor of the third ventricle, where they appear as white prominences. Great care must be taken not to disturb the

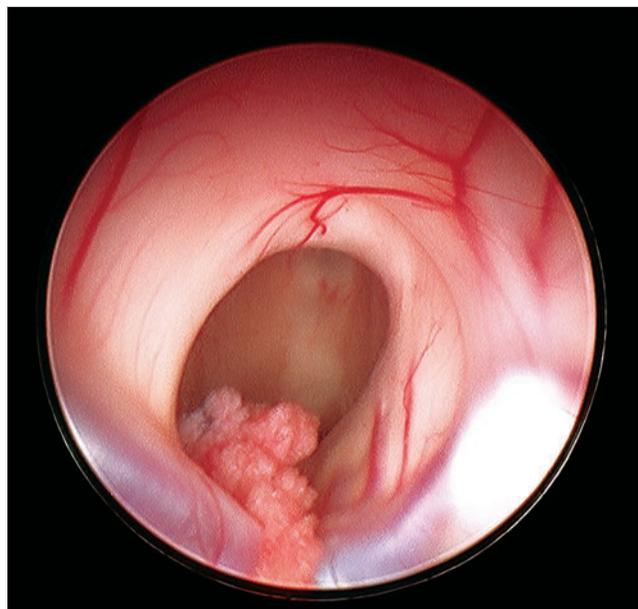

Fig. 11.2 Intraoperative anatomy seen during neuroendoscopy after the lateral ventricles have been entered. The foramen of Monro can be seen at the center of the image with the choroid plexus entering the third ventricle. The thalamostriate vein can be seen surrounding the posterior opening to the foramen of Monro, while the roof of the foramen is composed of fibers from the fornix. Damage to these fibers can be responsible for postoperative memory impairment.

fornices when the third ventricle is entered and the endoscope is manipulated.⁷⁵ As the third ventricle is entered, the anterior portion is appreciated, with the infundibular recess and anterior to it the optic recess. The tuber cinereum and the portion of the third ventricle between the mammillary bodies and the infundibular recess, is seen along with a vascular blush along the third ventricular floor. The tuber cinereum can be thinned out and stretched in the presence of hydrocephalus and may permit a view of the apex of the basilar artery in the interpeduncular cistern. The posterior third ventricle contains the aqueduct of Sylvius and posterior commissure, observation of which may be obstructed by a large massa intermedia. Visualization of these structures often requires changing the lens from a 0-degree scope to a 30-degree angled lens and turning a rigid endoscope around to look posteriorly.

11.4 Endoscopic Procedures

Intracranial endoscopic procedures can largely be classified as intraventricular and extraventricular applications. Conventional intracranial approaches utilizing the endoscope employ a bur hole or small craniotomy access through either one or several openings. The applications of neuroendoscopy continue to expand⁷⁶ in pediatric neurosurgery as investigators push the boundaries to define optimal patient populations.⁷⁷ Patient selection^{78–80} is clearly correlated with outcomes in a variety of neuroendoscopic procedures and ultimately determines their success in addressing pathologies.^{7,36} These approaches are largely driven by efforts to reduce manipulation of the normal cortex and minimize injury to surrounding neural⁵ and vascular structures with a minimally invasive approach.⁸¹ Endoscopy also seeks to reduce the postoperative length of stay, the length of surgery, and the morbidities and blood loss associated with open techniques.⁸² In some areas of pediatric neurosurgery, there continues to be debate⁸³ about the optimal approach and the role of neuroendoscopy.¹ In the following sections, a variety of neuroendoscopic procedures are discussed, along with the indications for surgical intervention and the subset of children who are potentially best suited for minimally invasive surgery.

The operating room setup for each endoscopic case depends on the approach being used. In general, however, the surgeons manipulating the endoscope and instruments should have the monitor placed in front of them so that their gaze is fixed on the screen and their access to surgical instruments is not obstructed (► Fig. 11.3). The surgeon holding the endoscope should have adequate room to avoid movement or disruption of the endoscope, with one hand firmly grasping the scope and the other on or near the cranium, ensuring that inadvertent plunging of the endoscope does not occur while instruments are introduced into the working channel.⁶⁶ When instruments are placed into the working channel, it is necessary to temporarily back out the endoscope a small distance to allow proper visualization of the instrument as it makes its way into the field of view. This prevents instruments from puncturing and damaging neural tissue outside the surgical field.⁶⁶ Additionally, the operating surgeons should verify the orientation of the lens if it is changed or added to the endoscope and should ensure that CSF has a proper egress from the brain by opening a working

Fig. 11.3 The endoscope and viewing screens are set up in a way that allows the surgeon to have maximal visualization of the ongoing operative procedure while also having access to the surgical instruments. The surgeon maintains fixation on the screen to ensure that no intracranial structures are damaged during endoscopic manipulation.

channel or appropriate port in the endoscope.⁸⁴ Finally, irrigation should be attached to the endoscope before the CNS is entered in order to avoid unnecessary twisting or manipulation of the endoscope. These small steps in endoscope setup help limit small-vessel or cortical hemorrhages throughout the endoscopic procedure.⁷⁵

11.4.1 Intraventricular Applications Third Ventriculostomy

The history of endoscopic surgery¹ to treat pathologies of the CNS is based upon the treatment of hydrocephalus with ETV.⁸⁵ Since its first use in 1922 by Dandy⁸⁶ as an open procedure, third ventriculostomy has undergone modification and is now incorporated into the realm of endoscopy as a standardly performed procedure.⁸⁷ The indications⁸⁸ for performing ETV normally include noncommunicating hydrocephalus with an open subarachnoid space for CSF uptake, although quantification of CSF absorption is difficult. Preoperative imaging⁶⁴ with MR imaging or CT reveals the presence of hydrocephalus and can help to determine if aqueductal stenosis or additional pathology is responsible for the obstruction in CSF flow.⁸⁹ MR imaging may reveal anatomical clues,⁹⁰ such as inferior bowing of the third ventricular floor, and can identify if the prepontine space⁹¹ is adequate for passing a blunt probe through the floor of the third ventricle. The location of the basilar artery can also be appreciated on sagittal MR imaging.⁹² Additionally, preoperative cine phase-contrast MR imaging gated to the cardiac cycle and performed in a midsagittal plane can qualitatively measure CSF velocity and flow and further identify the source and degree of CSF obstruction.^{93,94}

It was previously thought that in patients less than 1 year of age,¹⁶ myelomeningocele⁹⁵ (MMC)-related hydrocephalus, small ventricles, and infection of the CNS were contraindications to ETV.⁹⁶ However, studies⁹⁷ in each of these patient

populations have shown success⁹⁸ in reducing the proportion of patients who are shunt-dependent, suggesting that patient selection may not be as straightforward as one would hope.⁹⁹ Still, these more difficult scenarios must be taken into account when children and their parents are counseled as to the postoperative expectations with ETV.¹⁰⁰

ETV is performed under general anesthesia, and the patient is positioned supine with the head placed on a headrest elevated to about 30 degrees. The surgeon and assistant stand at the patient's head and look straight ahead at the digital monitor. If image guidance is being used, the authors prefer the head fixed in pin stabilization. The surgical site is prepared, and a small area in the midpupillary line just anterior to the coronal suture is marked about the coronal suture and make a bur hole or small craniotomy. The location of the bur hole may be adjusted by stereotactic localization in order to optimize the trajectory for making the third ventriculostomy and to observe any additional pathology that may be present.⁵¹ The authors prefer a more medial trajectory for ETV because it allows optimal visualization of the foramen of Monro and placement of the fenestration. The dura mater is opened, and the pia mater is coagulated and incised. The frontal horn of the lateral ventricle may be cannulated with a small needle or sheath of the endoscope to ensure that CSF is present.³³ CSF can then be collected for marker studies and histology if needed. The obturator in the sheath is removed, the endoscope is outfitted with a camera, and a light source is introduced. Irrigation tubing connected to the endoscope port allows lactated Ringer solution to enter the CNS, and an open channel allows CSF and fluid to exit.⁶⁶

The floor of the lateral ventricle and its ependymal surface are first appreciated along with the choroid plexus and foramen of Monro, which serve as landmarks for proceeding to the third ventricle (see ► Fig. 11.1).⁶⁷ The fornix is identified, and care is taken to avoid injuring this structure with instruments or the manipulated endoscope, because patients with forniceal damage may present with retrograde amnesia and verbal memory impairment postoperatively.⁴⁴ As the third ventricle is entered, the mammillary bodies are seen at the posterior aspect of the anterior floor along with the optic and infundibular recesses more anteriorly. The thin, translucent tuber cinereum contains only glial tissue and may be pulsatile from the underlying or adjacent basilar artery.¹⁰¹ A site of fenestration is chosen that is slightly more anterior^{14, 102} than halfway between the mammillary bodies and the infundibular recess. It is imperative to avoid vascular injury to the underlying basilar artery.

A 4F Fogarty balloon catheter with stylet or rigid probe is then passed down the working channel of the endoscope so that the end of the catheter can be seen in the operative field of view before it impacts any nearby structures on the floor of the third ventricle. The 4F balloon catheter is used to augment the opening (► Fig. 11.4a).^{82,103} The floor is then punctured at the desired site, with care taken not to plunge beyond the area of visualization. The opening is widened with balloon insufflation (► Fig. 11.4b). The endoscope can then be used to inspect the opening to identify the Lilliequist membrane,¹⁰⁴ an arachnoid plane containing the basilar artery complex and separating the posterior fossa cisterns from the suprasellar cisterns (► Fig. 11.4c).⁶⁸ This membrane must be opened to ensure

proper connection between the cisterns and the flow of CSF through the ETV. When the basilar artery complex and perforators are seen clearly, the pulsatile flow of CSF can often be observed through the opening in the third ventricular floor.¹⁰¹ Care must be taken around the opening of the floor of the third ventricle as excessive stretch may damage nearby basilar artery perforators or the hypothalamus, creating subarachnoid hemorrhage or autonomic disturbances, such as bradycardia.^{75,81,105} Laser perforation¹⁰⁶ has been utilized to open the floor of the third ventricle, but this may place adjacent vascular structures at increased risk for thermal injury during the procedure.⁴⁵ The authors advise against the use of laser perforation of the third ventricular floor.

The ventricles are inspected for any areas of hemorrhage and are copiously irrigated before removal of the endoscope. The patient is observed for 24 hours to ensure that flow through the ETV is adequate.^{101,107,108} Postoperative MR imaging¹⁰⁹ can determine the site and patency of the ETV, especially when it is combined with cine flow studies.⁹⁴ These images may be important to establish a new baseline for the affected child during subsequent evaluations. The ETV may not immediately affect ventricular size, and follow-up examination 6 weeks to 2 months later may reveal resolution of the ventriculomegaly.³⁷ Children may be followed intermittently¹¹⁰ in the postoperative period with MR imaging to ensure that ETV failure has not occurred. Long-term follow-up¹⁰⁰ may be required in certain cases as stomas in the floor of the third ventricle may lose patency, causing recurring symptoms and signs of elevated ICP.¹¹ In the setting of ETV failure, reinspection with an endoscope is warranted to determine the patency of the previous ETV and possible reopening of the closure. Occasionally, the stoma may be closed from gliosis¹¹¹ or infection, or plugged with cellular or proteinaceous debris, necessitating opening and exploration of the floor of the third ventricle. If the ETV is found to be patent, additional procedures, such as shunt insertion, may be required for poor CSF absorption in the subarachnoid space of the intracranial venous system.¹¹²

Outcomes¹¹³ of ETV vary depending on the definition of ETV success used by reports in the literature.¹¹⁴ ETV outcome studies describe primarily age and pathology as factors determining long-term outcome in children.^{14,103,115} ETV has also become a promoted therapeutic strategy for patients in underdeveloped countries^{82,116} to avoid the complications associated with shunts. The greatest success of ETV^{11,117} is seen in children with acquired, late-onset noncommunicating hydrocephalus resulting from tumor blockage¹¹⁸ of the aqueduct or fourth ventricle.¹¹⁹ The success rate for children meeting these criteria is as high as 80 to 90%.^{82,120-122} Lower success rates are reported in children less than 1 year of age^{110,117,123} or with a history that includes CNS infection, MMC, communicating hydrocephalus, the presence of a preoperative shunt system, or congenital aqueductal stenosis.^{14, 115,123} The presence of a shunt system¹²⁴ is not an absolute contraindication to attempting an ETV¹⁰⁸; ETV may allow the child to become shunt-independent. Also, approximately 50% of neonates with an MMC^{95,125} may respond to ETV, so that they are liberated from shunt placement in a disease that was once thought to be synonymous with shuntable hydrocephalus.¹²² ETV for children with an MMC^{81,95} may be complicated

by the abnormal intraventricular anatomy that is frequently encountered, necessitating conversion to placement of a ventriculoperitoneal shunt system. Such anatomical limitations include abnormalities in the skull base limiting the prepontine space⁹¹ and abnormal ventricular anatomy. The long-term cost-effectiveness¹⁰ of ETV in comparison to shunts, however, is an area of considerable debate, and additional studies are warranted⁸³ to determine its use in various populations of children.¹⁰

Complications arising from ETV^{37,45,117,123} include hemorrhage¹²⁶ from damage to the basilar artery, infection, midbrain injury, third nerve palsy, hemiparesis, neuroendocrine deficits from damage to the hypothalamic nuclei, subdural hematoma,

fever unrelated to infection, and damage to the fornix resulting in memory impairment.^{12,81} Many complications¹²⁷ are transient in nature and resolve in the immediate postoperative period on follow-up examinations.^{37,78,79,93,97,108}

Multiloculate Hydrocephalus

Multiloculate hydrocephalus and isolated ventricles can result from any inflammatory¹²⁶ or infectious¹²⁸ process within the cerebral ventricles and can lead to trapped CSF spaces that complicate the clinical presentation and treatment of a child with hydrocephalus. Isolated ventricles may result from overdrainage of CSF in infants, leading to slit-ventricle syndrome and

isolation of a lateral ventricle from the rest of the ventricular system.¹²⁹ Equilibration of the ventricular system may not occur after shunt placement, and overdrainage of the ipsilateral ventricle may cause the contralateral ventricle to dilate. Similarly, if the aqueduct of Sylvius collapses, a dilated fourth ventricle may develop, compressing the adjacent brainstem. Postinflammatory hydrocephalus results from infection or hemorrhage within the CNS and can lead to scarring of the subarachnoid spaces, decreased CSF absorption, ependymal cyst formation, and obstruction of CSF flow.¹³⁰ With its narrow gauge, the aqueduct of Sylvius is particularly vulnerable to occlusion from inflammation. Gram-negative ventriculitis and perinatal intraventricular hemorrhage may result in subependymal cyst formation that may later exert mass effect on the surrounding ventricles, impeding and ultimately obstructing CSF egress.^{48,131}

Patients with numerous cysts are more complex cases than those with uniloculate cysts as these children may have undergone numerous shunt revision surgeries necessitating multiple catheter placements to control expanding cysts. The ultimate goals in treatment, however, are similar in both cases; the objective is to provide communication and CSF flow between all isolated compartments with the ventricular system. Shunt placement in these patients is fraught with challenges¹³² as collapse of the cyst around the shunt catheter or scarring at its tip may obstruct CSF flow.¹²⁹ Balancing CSF pressures to prevent collapse and maintain flow is also difficult to determine with a shunt and its valve, leaving only trial and error and multiple surgeries as the answer to this dynamic problem.

In order to treat children with multiloculate or uniloculate hydrocephalus more effectively, pediatric neurosurgeons are turning increasingly to the use of endoscopy to reduce the need for shunts or to decrease the overall shunt burden in these patients. Endoscopic cyst fenestration aims at making sufficiently large holes (> 1 cm) in each cyst wall and having the cysts communicate with either the native ventricular drainage systems, if they are present, or with a shunt catheter.¹³³ Cyst walls are also devascularized to help reduce the potential for closure of the stoma. The fenestrations of multiple compartments in the ventricular system are not, however, straightforward, and surgeons employ additional technology to improve fenestrations into known compartments, avoiding unnecessary manipulation of nearby neural structures. One technology that has been utilized to guide cyst fenestrations is stereotactic management, in which each cyst wall can be verified before marsupialization. Intraoperative MR imaging^{51,130,134} may also be used in conjunction with endoscopy to reduce the number of isolated cysts present in the CNS and to ensure maximal communication between the multiloculate locations. If the child has open fontanelles, intraoperative ultrasound may also be used to verify the collapse of cysts throughout the brain.¹⁵

Before surgical intervention, preoperative MRI may improve the anatomical localization of each cyst wall in relation to the ventricular landmarks.⁵¹ The surgeon can plan multiple trajectories to determine the entry point in order to optimize the number of cysts fenestrated and identify an area where these can be made to communicate with the native ventricular system or with a shunt catheter to be left in place. Entry points can also be selected to avoid eloquent cortex and neurovascular structures, which would otherwise limit the fenestration attempts. Surgical access also depends largely on the location of the cysts;

those located in the anterior or body of the lateral ventricle require a precoronal bur hole, whereas those in the temporal or occipital horns may require a bur hole in the occipital region.¹³³ After the optimal trajectory has been planned, the patient is placed under general anesthesia and prepared, and the planned incision is made. Using a combination of blunt probes, forceps, scissors, and electrocautery, the surgeon creates cyst fenestrations through the involved areas. Landmarks on the floor of the lateral ventricle are identified but may initially be obscured by cyst walls. Verifying location throughout the process with stereotaxis⁵³ is essential to avoid collateral injury to nearby vital structures. At the end of the procedure, the ventricles are inspected for evidence of communication and for lack of hemorrhage, and if needed, a shunt catheter or ventriculostomy catheter is placed.¹²⁹

Endoscopy has been shown to significantly lower the shunt revision rate in multiloculate hydrocephalus,¹³³ and postoperative imaging may confirm the fenestrations made. Children should be followed carefully during the first several months after surgery to ensure that closure of the stomas does not occur.¹²⁹ Long-term follow-up studies with MR imaging may also indicate increased growth of particular cysts and track the equilibration process. Patients with multiple cysts may be up to seven times¹³⁰ more likely to need a repeated endoscopic procedure than patients who underwent endoscopic fenestration before shunt placement. Repeated endoscopic procedures for multiloculate cysts are required in up to 33% of cases; however, complex shunt systems for these patients could be simplified in 75% of patients.¹³⁵ Endoscopy reduced the need for cystoperitoneal shunt revision from 2.9 revisions per year to 0.2 revisions per year.^{20,41}

Alternative treatment strategies exist for an isolated fourth ventricle²² an aqueductoplasty with or without the use of stent assistance aims to introduce normal CSF flow through the aqueduct of Sylvius. A short segment of aqueductal stenosis is preferable¹¹⁹ when an aqueductoplasty is performed, and the surgical approach may originate through an anterior bur hole with access through the third ventricle. Alternatively, a suboccipital approach²¹ through the cerebellomedullary cistern may be used to access the foramen of Magendie.¹¹⁹ Stents placed in the aqueduct consist of normal ventricular shunt tubing that may be connected to subcutaneous reservoirs or existing shunt systems. Stents can be deployed with rigid, flexible, or flexible-in-rigid²⁵ endoscope arrangements.²² Care must be taken to avoid injury to adjacent structures in the midbrain²⁰ and to avoid prolonged occlusion of the cerebral aqueduct because it may result in bradycardia or neurologic deficits.¹⁰⁰

Arachnoid Cysts

Arachnoid cysts account for 1% of intracranial lesions, and with improved neuroimaging techniques in children, their diagnosis has increased. Arachnoid cysts are thought to be congenital, and their etiology and pathogenesis are unclear.^{28,39,51,136} These intracranial lesions may result from a one-way CSF valve, osmotic gradients within the cyst, or increased fluid synthesis from the cyst wall. Fifty percent of arachnoid cysts are located in the middle fossa; 10% arise in the cerebral convexity, 10% in the midline posterior fossa, 10% in the suprasellar cistern,¹³⁷ 10% in the cerebellopontine angle, and

10% in the quadrigeminal cistern.¹³⁸ Children may present with headaches, ataxia, seizures, or hemiparesis,¹³⁹ depending upon the size and location of the cyst, and they are at increased risk for spontaneous or posttraumatic hemorrhage into the cyst or into the subdural space.^{140,141}

The management of arachnoid cysts is controversial, and surgeons familiar with a particular approach frequently advocate endoscopy or microsurgical approaches.^{38,139,140,142,143} A review of arachnoid cysts treated with endoscopic techniques revealed that clinical resolution of symptoms was achieved in 90% following fenestration, and a decrease in cyst size was seen in 75% of patients. Postoperative complications were found in 16% of cases,³⁸ with the most common middle fossa cysts having the

highest recurrence and complication rates as well as the lowest clinical response rate.^{39,138} After fenestration (► Fig. 11.5), children with arachnoid cysts should be followed over several years for delayed recurrences. Similar success rates have been reported for cystocisternostomy and ventriculocystostomy²⁸ as for ventriculocystocisternostomy, in which communication is made between the basal floor of the cyst wall and the underlying cisterns.¹⁴¹ Quadrigeminal cysts¹³⁶ may compress the aqueduct of Sylvius and are amenable to endoscopic treatment because they are adjacent to the third ventricle. Patients with these cysts frequently present with macrocephaly, headaches, and ataxia. Fenestration options include ventriculocystostomy and ventriculocystocisternostomy, and success rates

range from 70 to 90%, depending upon the series and surgical methods utilized.¹³⁶

Shunting is also a therapeutic option, with cystoperitoneal shunt placement, but it may be associated with subdural hematoma formation from a rapid decrease in cyst size. Open surgery for cysts is frequently employed, and success rates vary from 54 to 96%. Open surgery is also associated with a 7 to 12% reoperation rate.²⁸ The advantage of using the endoscope in the treatment of arachnoid cysts is the minimally invasive approach, which avoids a larger craniotomy. Lower risk for hemorrhage and for altering the resorptive capacities of the subarachnoid space has been reported with the use of endoscopes. The success rate of neuroendoscopy in arachnoid cyst fenestration varies from 66 to 96% in the resolution of clinical symptoms and is 80% in reduction of cyst size.²⁸ One area in which endoscopic surgery has supplanted open microsurgical technique is in the treatment of pediatric suprasellar arachnoid cysts; success rates in the reduction of cyst size have improved while the comorbidities associated with an open procedure have been limited.¹³⁷ Failure rates for endoscopic cyst fenestration are similar to those of open microsurgical approaches, with rates ranging from 3 to 17%.³⁹ The optimal treatment for symptomatic and asymptomatic arachnoid cysts remains unclear, and it is hoped that future studies will continue to clarify the use of neuroendoscopy in children with these lesions.¹⁴⁴

Parasitic Cysts

Neurocysticercosis (NCC), resulting from infection with *Taenia solium*, is the most common parasitic infection in the CNS and can lead to hydrocephalus in approximately 30% of affected patients.¹⁴⁵ NCC is estimated to cause 50,000 deaths each year in Latin America, and parasitic cysts are often seen in the lateral and fourth ventricles in children, occluding the foramen of Monro or the cerebral aqueduct.²⁶ Noncommunicating hydrocephalus can result from the obstruction of CSF flow. Treatment for NCC infection includes antihelminthic medications such as albendazole, microsurgical removal of cysts, treatment with steroids and antiepileptic medication, ventriculoperitoneal shunting, and endoscopic retrieval of cysts.¹⁴⁶ Endoscopy is the favored treatment modality for patients with obstructive hydrocephalus, and various endoscope setups may be utilized to retrieve parasitic cysts in the fourth ventricle. Flexible endoscopes placed in rigid endoscopes utilize the advantages of each technology, with a flexible endoscope navigating the challenging anatomy of the fourth ventricle.²⁵ Aspiration devices in rigid scopes or flexible biopsy forceps to retrieve offending cysts are alternative setups in cases of NCC. Shunts have an estimated complication rate as high as 88%¹⁴⁶ in NCC, and the use of neuroendoscopy avoids these comorbidities. In addition, 84% of patients whose NCC is treated with endoscopy require only one surgery to address their hydrocephalus, thereby reducing the need for additional shunt procedures.¹⁴⁷

Intraventricular Tumors

Intraventricular tumors comprise an estimated 2% of all primary CNS tumors, and neuroendoscopy is increasingly used in biopsy for diagnosis and in resections. Intraventricular tumors in children include the following: astrocytoma, meningioma,

craniopharyngioma, ependymoma, giant cell tumor, choroid plexus papilloma or carcinoma, subependymoma, germ cell tumor, teratoma, lymphoma, primitive neuroectodermal tumor, and central neurocytoma.^{148–150} Endoscopes can be used in a variety of ways to address intraventricular tumors; biopsies can be performed alone or in concert with ETV CSF fluid diversion¹⁵¹ or tumors may be resected with the endoscope, and a variety of microinstruments have been developed to work within the ports of the scope.^{24,55,118,152}

The mainstay of neuroendoscopy in the treatment of intraventricular tumors is centered upon treating hydrocephalus, and this can be paired with biopsies¹⁵³ of the lesion. The alternative to endoscopic biopsies in children is the use of stereotactic biopsy.^{50,154} Large series of patients undergoing stereotactic biopsy report mortality rates of 1 to 4%, morbidity of 4%, and diagnostic accuracy of 91%.¹⁵⁴ Neuroendoscopy has lower mortality rates, variable morbidity rates ranging from 0 to 17%, and diagnostic accuracy ranging from 70 to 100%, depending upon the series.^{23,24,55,118,152,155} Rigid endoscopes are correlated with higher diagnostic rates than are flexible endoscopes.^{73,118,156} Endoscopic series of tumor biopsies may have higher morbidity rates because there is a larger opening affecting nearby neural structures, including the fornices, and because it is difficult to control the most common complications of CSF leakage and intraventricular hemorrhage. The advantage of endoscopy is direct visualization of the tumor in relation to other adjacent structures, allowing a full inspection of the anatomy before biopsy, whereas a stereotactic approach is essentially a blinded procedure guided by computer representations of the anatomy. Endoscopic biopsy has the added benefit of coupling tissue sampling with concurrent CSF diversion or tumor debulking.^{157,158} Recent studies on the administration of fluorescent dye to visualize tumors and improve the results of diagnostic biopsy are promising.¹⁵⁹

Frameless stereotactic systems can be combined with microsurgical and endoscope-assisted resections¹⁵³ of intraventricular lesions to improve localization and the amount of tumor resected.¹⁶⁰ Intraventricular tumors are frequently approached through an ipsilateral bur hole, with the tumor accessed through a dilated lateral ventricle.^{155,161} With technical innovations in surgical instrumentation, devices can now aspirate and evacuate tumor. Oscillating microdebriders,¹⁶² ultrasonic aspirators, and variable-aspiration resection devices can be deployed through the working channel to improve tumor manipulation and extirpation. The improvements in these devices continue to advance the surgeon's ability to remove tumors through the minimally invasive approach. Alternatively, endoscopy following the microsurgical resection of an intraventricular tumor allows a surgeon to inspect the resection bed for residual tumor. The variably angled lenses¹⁶¹ of the endoscope allow a wider field of view than that of an operating microscope and make it possible for the surgeon to confirm that a gross total resection has been achieved by peering around corners.³¹

Proponents of using the endoscope for the gross total resection of lesions have advised that lesions with moderate to low vascularity, soft consistency, size of less than 2 to 3 cm, low histologic grade, and location in the lateral ventricle are most amenable to resection via an endoscope.¹⁶³ The absence of hydrocephalus is not an absolute limitation to resection or an endoscopic approach to intraventricular lesions.⁷⁰ Hence,

decisions to attempt gross total resection of an intraventricular tumor must take into account the lesion's histology, size, location, and degree of vascularity. Outcome results for patients who underwent endoscopically assisted resection of pineal lesions have revealed shorter hospital stays and shorter surgical times, suggesting a potential advantage and future role for endoscopy in treating pediatric intraventricular lesions.¹⁶⁴

The most common locations for intraventricular tumor biopsies are lesions of the lateral and third ventricles as well as lesions surrounding the foramen of Monro.^{27,37,44,149,165,166} Exophytic tumors arising from the thalamus, mesencephalon, or basal ganglia may also warrant biopsy sampling; however, caution should be exercised because hemorrhagic complications during surgery may prompt conversion to an unplanned open procedure.^{155,167–169} Biopsies for intraventricular lesions are particularly useful when both CSF and tissue are needed for histologic analysis to exclude pathologies that may be amenable to radiotherapy or chemotherapy. CSF tumor markers for alpha fetoprotein and human chorionic gonadotropin may also be obtained.^{23,24} Endoscopic diagnosis of tumors like germinomas and lymphomas can alter the treatment course of children and ultimately lower the morbidity and mortality related to the surgical intervention.¹⁵⁸

Pineal Region Tumors

Pineal region tumors are one type of pediatric CNS tumor for which endoscopic biopsy is routinely used in tissue diagnosis.^{30, 155,169} Endoscopic approaches to pineal tumors have greatly enhanced the minimally invasive options for treating children with these lesions. Diagnostic biopsies with the endoscope are increasingly utilized to determine if chemotherapy, radiation, and microsurgery are warranted for a particular child's anticipated clinical course.¹⁵⁸ Pineal tumors have an incidence of 3% in the general population and comprise 11% of all pediatric tumors.¹¹⁸ Germ cell tumors are the most common pineal tumors, comprising 50 to 80% of lesions, and more than 50% of germ cell tumors are found to be germinomas. Pineal parenchymal lesions, including pineocytoma¹⁶¹ and pineoblastoma, occur in 7 to 14% of patients, and neuroepithelial lesions, such as gliomas, are the next most common diagnosis, occurring in 2 to 8% of patients. In children, 50 to 60% of tumors diagnosed with pineal tumor biopsy were found to be sensitive to chemotherapy or radiation therapy.⁵⁵

Diagnosis with this minimally invasive approach avoids the permanent morbidity of 10% associated with the open microsurgical resection of pineal lesions and the estimated 2% complication rate reported with stereotactic biopsy. In a review of the literature, endoscopy yielded a definitive diagnosis in 89% of cases, a number that may depend upon expertise among endoscopists.^{55,118} Neuroendoscopy for pineal region tumors also allows ETV for CSF diversion in the same surgical setting because 90% of patients with a pineal tumor present with hydrocephalus.¹⁵⁵ The ETV and biopsy procedure may be performed through a single bur hole, splitting the distance between a pre-coronal bur hole,¹⁵³ the site commonly used for an ETV, and a bur hole at the hairline, the site commonly used for pineal region biopsy.¹⁷⁰ A single bur hole is optimal when the lesion is anterior to a small massa intermedia and when the ventricles are dilated.

Colloid Cysts

Colloid cysts can sometimes be managed endoscopically. Colloid cysts are benign intracranial lesions and account for 1% of all intracranial neoplasms.⁴⁷ They can present with symptoms and neurologic deficits consistent with elevated ICP, and sudden death in patients, presumably from acute hydrocephalus and obstruction of the foramen of Monro, has been reported. With the increasing use of cranial MR imaging, colloid cysts are found incidentally, leaving an ongoing discussion about the parameters that necessitate operative intervention.³⁴ Traditionally, these lesions have been resected with microsurgical techniques through a transcortical and transventricular approach or a transcallosal approach.⁶² The authors prefer a bur hole that is more anterior and lateral than the midpupillary line in the endoscopic treatment of colloid cysts because this allows optimal visualization of the colloid cyst. A more medial approach may limit the resection or obscure portions of the cyst wall. Endoscopic resections have emerged as a minimally invasive treatment option for these lesions (► Fig. 11.6a,b). Endoscopic approaches are advocated because of the proposed decreases in risk of postoperative seizures from cortical manipulation, in operative time, and in hospital stay.²⁶ Open microsurgical techniques are associated with a 5% risk of seizures, whereas endoscopically guided colloid cyst removal has approximately a 1% risk for postoperative seizures. One of the most common complications of endoscopic resection that has been reported is impaired memory in 5% of cases¹⁷¹ and is attributable to manipulation of the adjacent fornices, prompting a critique as to whether the cyst capsule should be completely removed.¹⁷² Studies have also been performed on the imaging characteristics of colloid cysts and whether they dictate surgical management decisions, with hypointensity on T2-weighted MR images predicting recurrence of endoscopically resected lesions.¹⁷¹

11.4.2 Extraventricular Applications Craniosynostosis

One developing area that has generated considerable discussion¹⁷³ regarding endoscopic treatment options is craniosynostosis repair in children. Cranial remodeling for premature suture fusion is commonly performed by pediatric neurosurgeons; craniosynostosis has an estimated frequency of 0.4 in 1,000 live births. A majority of children present with involvement of single suture, most commonly the sagittal suture.^{174, 175} Surgeries involving removal of fused sutures began in the 1880s and continued to develop with more advanced techniques until the pioneering work done by Tessier in the 1970s, in which larger portions of the calvaria were removed and remodeled and fixed to allow compensatory growth. As experience with these surgeries continued to improve, certain limitations (operative time, blood loss, and the need for extended postoperative hospital admissions) became apparent. In 1999, the endoscopic approach to sagittal suturectomy was introduced and was reported to reduce the aforementioned variables. Children undergoing this treatment then required postoperative helmet orthoses to help maintain and guide desired calvarial relationships. This technique has since been adapted to other sutures, including lambdoid, metopic,

coronal, and multisuture¹⁷⁶ forms of synostoses, with varying results. There is now extensive experience across many centers with this procedure, and reports on surgical technique continue to improve.¹⁷⁷

Surgeons advocating endoscopic correction postulate that earlier correction in children younger than 3 months of age is desirable to prevent the secondary deformational changes that accompany synostosis. The advantages of reducing blood loss and perioperative edema^{175,178} and of obtaining improved head shape based on anthropometric data¹⁷⁶ are well documented. There are, however, potential disadvantages with the endoscopic procedures that should be considered when families with affected children are counseled.¹⁷⁵ The success of obtaining a desired head shape is contingent on using helmet or band therapy and requires a family's commitment to the treatment. Ultimately, the outcomes of cranial remodeling are difficult to assess,¹⁷⁹ but parent satisfaction with endoscopy results continues to improve.

Skull Base Surgery and Endoscopic Endonasal Surgery

Endonasal approaches continue to expand the use of neuroendoscopy in pediatric neurosurgery.^{180,181} Conventional transphenoidal skull base surgery utilizes sublabial and transnasal approaches; however, in an attempt to increase the field of view and improve visualization of the sella turcica and adjacent

structures, surgeons are turning to neuroendoscopy. There are several advantages of this approach over conventional open micro-neurosurgery, including early exposure of the skull base and dura, lack of a large cranial opening and craniofacial scar tissue formation, and shorter hospitalizations. Several groups have pioneered endoscopic endonasal transsphenoidal surgery and have extended its application to address nearby pathologies by utilizing transsellar, transcribriform, transclival, and transodontoid approaches.¹⁸² The transsellar and transplanum approaches are commonly used for sella-based lesions, including pituitary adenomas, craniopharyngiomas,^{183,184} meningiomas, germinomas, and Rathke cleft cysts.¹⁸⁰ Maximizing the sphenoidotomy, posterior ethmoidectomy, posterior septectomy, and middle turbinectomy can create working space for extended surgical manipulation and the resection of lesions that previously required open craniotomies.¹⁸⁵

With endonasal approaches, it is possible to obtain openings in the sellar floor that extend from the cervical spine to the cribriform plate, while the lateral boundaries are defined by the carotid arteries, cavernous sinus, and medial orbital walls.¹⁸⁶ These exposures are not without risk, however, and require an appreciation of the carotid arteries and their relationships to the optic chiasm and pituitary gland. The optic canals serve as a landmark as they emerge in a posteromedial trajectory in the orbital apex, and the optic nerves mark the lateral limit of the transplanum approach. Other landmarks in the bone along the sellar floor include the carotid protuberances and the

optocarotid recesses, which correspond with the pneumatized portion of the anterior clinoid.^{63,185,187} Depending upon the age of the child, these landmarks may not have fully developed, and inability to appreciate the structures may make the surgery more difficult. The ethmoid sinuses enlarge by 3 years of age and are fully formed by 16 years of age, while the cavity of the sphenoid sinus starts to develop at age 4 and becomes fully developed by puberty.¹⁸ Intrasellar pathology may also expand, dehisce, and alter normal bone anatomy, shift vascular structures, or tether cranial nerves and further complicate endoscopic endonasal exposures.

Although surgeon experience with midline skull base lesions and relevant anatomy⁶³ is critical, there are lesions that obviate an endoscopic approach in children. Brain invasion, diffuse cavernous sinus involvement, encasement of the carotid arteries and cranial nerves, and extensive intradural or intraventricular extension are several factors that may necessitate a craniotomy.^{58,188} Access to these types of lesions can be difficult with angled instruments, as can adequate control of hemorrhage in the event of neurovascular injury.¹⁸ Preoperative skull base imaging with MR imaging and CT¹⁸⁹ better defines anatomical landmarks and septa in the bone leading to the exposure of the sellar floor. A careful study of preoperative images will yield a better understanding of the relationships between the normal pituitary gland, optic chiasm, hypothalamus, carotid arteries, and diaphragma sellae in relation to the lesion of interest. Stereotactic imaging⁵² identifies the midline, orients the surgeon, thereby preventing inadvertent damage to the nearby carotid arteries and optic nerves, and optimizes the extent of surgical resection for a lesion. Angled endoscopic lenses allow the surgeon to peer around corners and inspect resection beds of residual tumor.

Endoscopic endonasal surgery has had an evolving role in adult patients.¹⁸³ However, fewer studies are available in children.¹⁸⁸ The limitations of the use of endoscopic endonasal surgery in children arise from a decreased prevalence of amenable lesions and different anatomy; children have limited corridors for nasal access, with small nostrils and narrow nasal cavities, and less pneumatization of the sinuses. Because of the restricted access, a neurosurgeon and an assistant must utilize both nostrils in order to resect midline skull base lesions. The recent development of narrower-gauge endoscopes⁵⁶ may address some of the anatomical hindrances and obstacles facing the surgical team. The preoperative embolization¹⁹⁰ of larger tumors¹⁹¹ also has made it possible to expand the role of endoscopy in children and has the potential to avoid the need for larger craniofacial or transfacial approaches, which can result in facial asymmetry.¹⁸¹ Studies in children suggest that gross total resection is achievable in up to 60 to 81% of carefully selected cases for pituitary adenomas, craniopharyngiomas^{183,192,193} with sellar or infradiaphragmatic origins,¹⁸⁴ Rathke cleft cysts, juvenile nasal angiofibromas,^{182,191} and clival lesions.^{18,188} Repair of skull base defects resulting from trauma, congenital defects, or iatrogenic etiologies and leading to CSF leak is frequently addressed with endoscopic exploration and repair.¹⁹⁴

Similarly, surgeons are now more familiar with how best to address complications that arise from endoscopically assisted transsphenoidal surgeries. CSF leakage can be reduced by the application of a vascularized nasoseptal flap covering the skull base defects in order to optimize healing and can be paired

with nasal packs to buttress the repair. These measures may require the presence of a lumbar drain for CSF diversion if revision is necessary.^{181,182,193} Although limited by the decreased prevalence of the aforementioned diseases in children, endoscopic endonasal surgery in pediatric patients is feasible, and additional studies will determine the optimal parameters for selecting patients to undergo minimally invasive endoscopic approaches.

Intraparenchymal Lesions

Hypothalamic hamartoma is one type of intraparenchymal lesion that has been treated endoscopically with considerable success.¹⁹⁵ Hypothalamic hamartomas are congenital lesions that have an incidence ranging from 1 in 100,000 to 1 in 1 million and that frequently cause gelastic seizures or seizures that begin early in infancy.¹⁹⁶ Seizures from hypothalamic hamartomas are primarily refractory to current medical treatment, and patients often require surgical intervention and resection of the lesions with disconnection from the mammillary bodies.¹⁹⁷ Resection of the lesions has been found to reduce and, in most cases, to eliminate seizures.⁶⁰ Several groups have reported their results on complete or partial hamartoma resection with the neuroendoscope.^{195,198} A contralateral approach is used with the endoscope to promote visualization of the border between the lesion and the surrounding hypothalamus. In a majority of the patients treated with this approach, seizure frequency was reduced, and the seizure-free rates were not significantly different from those achieved with a transcallosal anterior interforaminal approach. The benefit of endoscopy continued to be shorter hospital stays in comparison with open microsurgery.^{196,197} Endoscopy for other epilepsy surgeries, such as corpus callosotomy and hemispherotomy,¹⁹⁹ has been illustrated in cadaveric experiments and may be amenable to translation in pediatric cases.

Several groups have utilized the endoscope to resect intraparenchymal tumors⁴⁰ in adults and children.^{59,69,164} More recently, a tubular retraction system,²⁰⁰ or port,²⁰¹ has been used to aid in tumor visualization with an endoscope-alone procedure. The port, when paired with stereotactic guidance, has been successfully employed to resect intraparenchymal lesions.²⁰² These tubular retraction systems offer the advantage of minimal retraction of the surrounding cortex with improved optics and bimanual use of instruments. Another use for endoscopy in the removal of tumors is the endoscope-assisted method^{203,204} in which the endoscope is introduced to inspect resection sites for residual tumor, to resect smaller and more inaccessible areas of tumor growth, and to look around corners.⁵⁹ Pediatric neurosurgeons continue to explore the applications of endoscopy for tumor removal in patients with various pathologies.^{27,159–161,164,198,205}

The endoscopic evacuation of spontaneous intracerebral hemorrhage is an alternative to craniotomy with hematoma evacuation.^{43,71,206,207} First described in 1985 by Auer,²⁰⁷ several studies have described the feasibility of endoscopic hematoma evacuation in adults. Endoscopy in the early stages (less than 24 hours after hemorrhage) may prevent the clotting of blood, which makes aspiration of the clot more difficult. Minimally invasive evacuation of a hematoma with an endoscope offers several advantages in decreasing the amount of injury to overlying normal

cortex, especially in the case of a deep-seated hematomas in eloquent cortex. Endoscopic approaches have been shown to shorten the surgical time, reduce the number of hospital days in an intensive care unit, and possibly improve or hasten the neurologic recovery of adult patients in comparison with patients undergoing craniotomy for evacuation.⁴³ Surgical techniques have been developed to treat intraoperative hemorrhages during clot aspiration in which surgeons remove the most distal region of hemorrhage first to prevent collapse of the cavity. Nagasaka et al describe a method combining an irrigation–coagulation suction cannula²⁰⁸ with an irrigation–suction technique. Although repeated irrigation will control small hemorrhages during surgery, an alternative method in which the combined irrigation–coagulation suction cannula is used is to identify the perforating artery with irrigation, trap it with suction, and then coagulate it. An additional method to aid inspection of a hematoma cavity is to fill the cavity with irrigation fluid and identify the bleeding arteries. Current evidence²⁰⁹ supports the endoscopic evacuation of hematomas with minimal risk and with efficacy. Future studies in children are warranted.

Finally, intracranial abscesses have been approached with various surgical treatment modalities, including stereotactic aspiration with drainage. Although not the first line in treatment options, the endoscope has been employed for abscess evacuation.¹⁵⁴ The proposed advantage of utilizing neuroendoscopy coupled with stereotactically guided aspiration is that the surgeon is able to visualize the drainage to ensure complete evacuation. Endoscopy may be advantageous in the event of multiseptate abscess or subdural empyemas, or in the intraventricular evacuation of purulent material. Few studies using endoscopy have been performed, and additional studies will be required to determine its effectiveness in treating intracranial abscesses.²¹⁰

11.4.3 Other Applications

Spinal applications^{194,211–213} for endoscopy continue to expand each year, with the focus on minimally invasive treatment of spinal pathologies. Endoscopy has been utilized in the treatment of herniated intervertebral disks,^{214,215} placement of spinal instrumentation,²¹⁶ treatment of idiopathic scoliosis,²¹⁷ fenestration of intramedullary spinal cysts,²¹⁸ suboccipital decompression for Chiari malformation,²¹⁹ transnasal odontoidectomy,⁵⁷ transoral and transcervical approaches to the craniovertebral junction,^{220–222} and intradural resection of spinal cord tumors and split-cord malformations.²¹¹ Although larger studies for each application are warranted to determine efficacy, the neuroendoscope is not limited to cranial applications in children.

11.5 Complication Avoidance and Management

One of the essential aspects of working with neuroendoscopy is to realize its limitations²²³ when surgeons are manipulating tissues in limited corridors deep within the brain. Rapid access to these areas of the CNS can be hindered by the presence of adjacent critical neural structures and eloquent cortex. Potential intraoperative complications²²⁴ and strategies for their management should be considered before their occurrence and a contingency plan should be identified should additional meth-

ods be required.¹¹⁴ Although the previous sections have illustrated the diverse set of neuroendoscopic applications and a promising future in addressing a variety of pathologies, great care must be taken to consider the neurovascular implications of injury to adjacent structures.²²⁵

One of the most common intraoperative complications during intraventricular neuroendoscopy is hemorrhage,⁵⁵ which can vary in severity depending upon the size of the arteries or veins disturbed during surgical manipulation. Intraventricular hemorrhage is a nuisance in endoscopic procedures because the clear anatomy quickly becomes opacified and surgical navigation within the ventricle is hindered. Identification of the source of the bleeding is the first step to stopping the hemorrhage and clearing the operative view.^{121, 150, 152} Hemorrhage may result from injury to small cortical vessels during introduction of the endoscope into the ventricles or manipulation at the cortical surface. In addition, small perforators may be damaged during the manipulation of intraventricular lesions, such as colloid cysts and tumors,¹⁶⁶ or during ETV.^{81, 96} These small-vessel hemorrhages, even if persistent, usually respond to tamponade with the endoscope or balloon catheter⁷⁰ or to gentle irrigation. Electrocautery may be used if the vessel can be seen at the cortical surface, and persistent irrigation within the ventricle may help identify a deeper source of bleeding. Bipolar electrocautery may also be employed if the hemorrhage is more brisk.⁷³

When a more persistent torrent of blood is seen, a larger vessel has been injured, and gentle and persistent irrigation may not be adequate to stop the source. If after persistent irrigation the field continues to be filled with blood and identification of the source is not possible,²²⁶ there is the option to convert the procedure to an open craniotomy, widening the exposure and introducing the surgical microscope by creating a small craniotomy followed by placing a ventriculostomy to aid in the drainage of blood products. However, leaving a ventriculostomy²²⁷ when the surgical field has occasional small areas of hemorrhage and adequate hemostasis has not been obtained may place children at additional risk for persistent intracranial hemorrhage.¹²⁰ The ventriculostomy will allow drainage and measurement of the ICP¹⁰⁷ for an early warning of persistent intraventricular hemorrhage. Thankfully, with experience, conversion² to an open procedure is not a frequently encountered problem; however, before surgery, contingency plans for such an event should be made. Early postoperative cranial imaging with head CT is recommended should there be an area of concern. If a large vessel like the basilar artery⁷⁵ has been compromised during neuroendoscopy, then endovascular approaches may be required, and the appropriate consultation should be obtained for emergency evaluation.

An additional aspect to working with endoscopes that is persistently encountered is failure of the equipment during a procedure.⁵² The lenses of the endoscope may become compromised along with the digital imaging; in addition, sheaths, endoscopes, and microinstruments may be bent or impossible to place in the appropriate port for use. If these situations occur, backup instrumentation and scopes should be readily available. Proper maintenance and training in the handling of endoscope equipment for all staff should help to minimize equipment failure. The surgeon should also have a routine for checking that the equipment is available, intact, and connected in the proper

orientation before making an incision or introducing the endoscope into the CNS. This may help to prevent excess manipulation in and out of the brain.⁸⁷

Loss of orientation may occur during surgery and may result from failure to check the proper lens orientation before placing the scope in the sheath, utilizing an inappropriately angled lens, or failure of the stereotactic localization. Hemorrhage and unfamiliar anatomy may also lead to error. If disorientation occurs, it can lead to mistaking the anatomy of the ventricle and placing the ETV posteriorly and 180 degrees from the desired location. Similarly, during cyst fenestrations, tissue adjacent to the stoma may serve a critical function in the thalamus or globus pallidus.^{133,140,228} Stereotactic localization may aid in preventing missteps.⁵³ Irrigation may also be used to test the movement of the underlying tissue to help determine whether the tissue is solid or part of a cyst wall. If the stereotactic localization has been compromised, anatomical landmarks become crucial, and the foramen of Monro and choroid plexus, if present, may serve as beacons for orientation. In addition, surface anatomy of the zygoma, sagittal suture, midpupillary line, tragus, andinion may be utilized to verify location and orientation during surgery. The surgeon should cease advancing the surgical instruments should disorientation occur and attempt to re-establish familiar landmarks.

11.6 Conclusion

Applications of neuroendoscopy continue to emerge rapidly in pediatric neurosurgery and have a promising future. As minimally invasive approaches achieve maximal and favorable outcomes, more and more surgeons are adopting these techniques for the care of their pediatric patients. Although endoscopic applications continue to push the limits and offer exciting new areas of investigation and instruments for surgical resections, restraint is needed until their efficacy²¹³ in children has been determined. The technology has outpaced our understanding of the clinical outcomes in certain areas⁸³ of pediatric neuroendoscopy, and we are charged with validating early studies with future work. Additional discourse and surgeon training will help to establish guidelines for training¹⁷³ and for patient selection.^{14,37,42,74,79,113,175}

Pearls

- The role of neuroendoscopy for the treatment of various pediatric neurosurgical diseases, which include intraventricular tumors, cyst fenestrations, and craniosynostosis, continues to expand. Neuroendoscopy also has applications in intraparenchymal procedures, skull base surgery with endonasal approaches, and spinal surgery.
- Anatomical landmarks should be identified and serve as beacons throughout a procedure. Such structures include the choroid plexus of the lateral ventricles, the foramen of Monro, the fornices, and the cerebral aqueduct.
- A preoperative routine of checking the instruments and orientation of the lenses will help avert missteps and disorientation intraoperatively.
- Management of potential complications should be considered before surgery so that a contingency plan is in place.

12 Intraventricular Hemorrhage and Post-Hemorrhagic Hydrocephalus

Jeffrey R. Leonard and David D. Limbrick Jr.

Intraventricular hemorrhage (IVH) remains the most common severe neurologic complication of preterm birth and presents significant life-long challenges for affected individuals. Approximately 12.1% of children born in the United States are born preterm, and very low-birth-weight infants are the most likely to develop IVH.¹ At the time of its publication in 1978, the landmark paper by Papile et al documented that 45% of low-birth-weight infants developed IVH.² Although marked improvements in medical care of the newborn have resulted in considerably lower IVH rates (currently 15 to 20%), the neurologic outcomes of infants who experience IVH are among the worst in neonatal medicine.^{3,4} Post-hemorrhagic hydrocephalus (PHH) occurs in up to one-half of those with IVH and is associated with a three- to fourfold increase in the risk for cognitive and psychomotor disability. Infants with PHH who require ventriculoperitoneal (VP) shunts have the worst neurologic outcomes, however, with neurodevelopmental impairments observed in more than 85% of infants and cerebral palsy in nearly 70%.⁵ In the current chapter, we review the recent literature regarding state-of-the-art diagnostic modalities, surgical and nonsurgical treatments, and outcomes observed in treating this disease. For additional information on the topics discussed herein, we refer the reader to the recent comprehensive review published by Dr. Shenandoah Robinson.⁶

12.1 Epidemiology

In tracking the effect of advances in antenatal, perinatal, and neonatal care over the past two decades, the Neonatal Research Network recently reported a survival rate of 92% for infants born before 28 weeks' postmenstrual age (PMA).⁴ IVH occurred in 16% of very preterm infants, with the incidence of IVH demonstrating an inverse correlation with PMA.⁴ The classification of IVH in premature infants is listed in ► Table 12.1. At 22 weeks' PMA, 30% of preterm infants had IVH; conversely, at 28 weeks' PMA, only 3% of patients had IVH.⁴ When the incidence of IVH in preterm infants was considered by grade,² 48% were classified as having grade 1 IVH, 18% had grade 2 IVH, 15% had grade 3 IVH, and almost 19% had grade 4 IVH.⁷ Although reports vary somewhat, it is estimated that 25 to 50% of infants with IVH develop post-hemorrhagic ventricular dilatation requiring neurosurgical treatment.⁸ As previously noted, severe IVH is associated with significant neurologic disability, particularly in those infants who develop PHH and require a VP shunt.⁵ These children frequently have severe cognitive impairments, cerebral palsy,⁹ and in many cases seizure disorders.^{1,10}

12.2 Pathophysiology

Alterations in blood flow to the developing germinal matrix microvasculature are believed to be the pathophysiologic

basis of IVH in premature infants.⁸ At the age when IVH is most likely to occur, key elements of the blood-brain barrier, including tight junctions, basement membrane, glial foot processes, and other supporting cellular structures, remain incompletely developed, leaving microvessels susceptible to disruption.¹² Thus, when hypotension, hypoxemia, or other systemic insults occur, corresponding changes in cerebral blood flow in the germinal matrix may result in hemorrhage into the surrounding tissue and/or the ventricle. In support of this concept, a retrospective case-control study matching premature infants with and without hypotension found that hypotension was a risk factor for the development of IVH and neurologic injury.¹³ Furthermore, if significant parenchymal hematoma is present, particularly in combination with ventricular distention, parenchymal infarction also may occur (grade 4 IVH).⁸

In cerebrovascular development, vessel growth and maturation progress from the pial surface and extend into the parenchyma, a factor that may contribute to the susceptibility of the deep white matter to hypoperfusion during the newborn period.¹⁴ Additionally, the capacity for autoregulation, which is mediated primarily by small cerebral resistance vessels, develops relatively late, limiting the ability of these small vessels to attenuate alterations in cerebral blood flow.^{15,16} Data from experimental models confirm this temporal sequence, with regulation of blood flow to the germinal matrix improved with increasing gestational age.¹⁷

In the setting of hypotension, hypoxemia, hypercapnia, or acidosis, cerebral blood flow appears to be affected to a large degree by inflammatory mediators like transforming growth factor- β (TGF- β), interleukin-6 (IL-6), tumor necrosis factor- α (TNF- α), and other factors that affect the cyclooxygenase pathway (COX-2).⁶ Proinflammatory molecules affect not just cerebral blood flow but also blood-brain barrier permeability via the disruption of tight junctions and specific barrier proteins.¹² Growth factors, cytokines, nitric oxide, and other molecules mediate these and other events, such as leukocyte endothelial

transmigration and activation of microglia; in turn, reactive oxygen species are produced that cause endothelial injury and parenchymal infarction.^{18,19}

Evidence is accumulating to suggest that genetic factors also may play a role in IVH. Gould et al have shown that mutations in the collagen 4A1 gene result in IVH in experimental models and are associated with hemorrhage and porencephaly in infants.^{20,21} Additionally, genetic mutations associated with thrombophilic conditions, such as mutations in the genes for prothrombin and factor V Leiden, also have been implicated in IVH and porencephaly.^{22,23} Finally, polymorphisms or mutations in the genes for proinflammatory cytokines, such as IL-6 and TNF- α , may also be involved in the pathogenesis of IVH, although this is controversial.^{24–26} It is likely that additional candidate genes with etiologic involvement in IVH will be identified in the near future.

The mechanism(s) by which IVH results in hydrocephalus (PHH) remains to be determined. Although PHH may have both obstructive and nonobstructive components, the condition generally results at least in part from impairment of cerebrospinal fluid (CSF) absorption at the level of the arachnoid villus or other absorptive pathway. In preterm infants, arachnoid granulations are immature and thus capable of undergoing robust fibrosis from the blood products or inflammatory mediators associated with IVH.²⁷ Blood degradation products and debris are thought to initiate an inflammatory process consistent with chronic arachnoiditis whereby laminin, collagen, and other extracellular proteins are deposited throughout the ependyma and subarachnoid spaces.²⁷ TGF- β and other cytokines, together with free radical elaboration, trigger a cascade of arachnoid fibrosis and ependymal–subependymal gliosis.²⁸ In support of this hypothesis, infants with PHH have been found to have significantly higher levels of TGF- β_1 and an aminoterminal propeptide of type 1 collagen in their CSF.^{29,30} Vascular endothelial growth factor (VEGF) has also been implicated in the pathogenesis of PHH, although its role is less well understood.¹² In many cases, this inflammation-based impairment of CSF absorption is compounded by ventricular outflow obstruction due to blood clots and debris within the ventricular system.

The effect of IVH and PHH on neurodevelopment is multifactorial. The period in which IVH occurs (before 34 weeks' PMA) is a critical neurodevelopmental interval, and neurologic injury during this time is likely to impair the proliferation and migration of neural precursors, neurite outgrowth and myelination, and functional network development.³¹ Clearly, the combination of ischemia–infarct and hematoma in germinal matrix is likely to cause significant injury to the nests of glial and neural precursor cells that reside in the subependymal zone.³¹ Furthermore, inflammation, cellular infiltration, and the generation of free radicals cause damage to the periventricular white matter and contribute to scarring and leukomalacia.^{32,33} Particularly in the setting of PHH, local increases in pressure and anatomical parenchymal distortion may affect development in the adjacent periventricular region, while a global increase in intracranial pressure (ICP) may impair cerebral perfusion and cause ischemia.⁶

12.3 Clinical Presentation

IVH may range from clinically silent to catastrophic, but most cases that go on to require neurosurgical attention take a

Sutures	Split
Head circumference	Crossing percentile curves

saltatory course, with hemorrhage occurring within the first hours to days after birth and then progressing for days to weeks.^{3,6} IVH is frequently diagnosed via screening cranial ultrasound and then monitored clinically. Although IVH may be associated with neurologic changes (e.g., decreased level of arousal, motor asymmetry, hypotonia, others), the development of PHH and thus increased ICP is heralded by changes in cranial parameters, including a bulging fontanel, increasing head circumference, and splaying of the cranial sutures. All of these metrics are examiner-dependent and somewhat subjective, but splaying of the sagittal suture may be the most reliable indicator.⁶ Later in the disease course, nonspecific but serious signs, such as apnea, bradycardia, and decreased spontaneous activity, may be observed (► Table 12.2). In cases of rapidly expanding hydrocephalus, ventricular enlargement may outpace increases in head circumference because of the relative compressibility of the white matter.³⁴

12.4 Imaging of Neonatal Hydrocephalus

At many centers, cranial ultrasonography is the primary imaging modality used to screen preterm infants for IVH. Cranial ultrasonography avoids ionizing radiation, is performed at the bedside, and permits adequate visualization of intracranial hemorrhage within the neonatal intensive care unit. The American Academy of Neurology practice parameter for neuroimaging of the neonate states that cranial ultrasonography should be performed at two time points (7 to 14 days and 36 to 40 weeks' PMA) to look for IVH, ventriculomegaly, and/or periventricular leukomalacia.³⁵ Widely accepted measurements of ventricular size used in preterm infants include the ventricular index,³⁶ anterior horn width, and thalamo-occipital distance.³⁷ Normative data for these ventricular measures in the preterm infant are available; however, the optimal threshold for clinical treatment has not been determined.^{36,37}

Magnetic resonance (MR) imaging is the method of choice for providing anatomical detail in the developing brain. Computed tomography (CT) is generally avoided when possible in the preterm infant because of the risks associated with repeated exposure of the developing brain to radiation.³⁸ Conventional T1- and T2-weighted MR sequences provide high-resolution images of the ventricular system and of cortical and subcortical structures, and MR imaging has become an essential part in the evaluation of neurologic injuries and congenital malformations in the newborn. In recent years, advanced MR imaging techniques, such as diffusion tensor imaging (DTI), also have been developed to assess subtle alterations in white matter integrity that remain undetected by conventional MR imaging sequences. Diffusion tensor imaging measures the magnitude and

directionality of water displacement in tissue and provides quantifiable measures of diffusion, fractional anisotropy, and mean diffusivity. Fractional anisotropy shows an exponential increase with neurodevelopment, whereas mean diffusivity shows a corresponding decrease during this interval.³⁹ Deviation of fractional anisotropy and the apparent diffusion coefficient from normative values is indicative of white matter damage, as demonstrated in various neurologic disorders, including hydrocephalus.^{40,41} Whereas DTI is used to examine static white matter microstructure, resting-state functional connectivity MR imaging (fc MRI) utilizes low-frequency (<0.1 Hz) fluctuations in the blood oxygen level-dependent (BOLD) signal to explore the functional neuronal networks.^{42,43} Although preliminary, fc MRI is now being applied in preterm infants to study the effect of newborn brain injury on functional cerebral architecture, and specifically the effect of pressure-based deformation in PHH on short- and long-term neurologic outcomes.

12.5 Clinical Treatment

12.5.1 Prevention as Treatment for Post-Hemorrhagic Hydrocephalus

Prevention of IVH and thus PHH is a primary goal in care of the preterm infant, and significant progress has been made in this regard. As noted above, a number of risk factors for IVH have been identified: early PMA and maternal hemorrhage/infection/inflammation, history of sepsis, hypotension, hypoxemia, hypercapnia, acidosis, pulmonary hemorrhage or pneumothorax, and respiratory distress syndrome (reviewed by McCrea and Ment).¹² It follows that prevention of IVH is best achieved by preventing or mitigating these conditions. Of particular interest, lack of antenatal steroid treatment during preterm labor has been shown to be a risk factor for IVH, and a number of studies have shown that antenatal steroid administration reduces the risk for IVH.⁴⁴ The mechanisms underlying this finding remain to be determined; however, it is likely that steroids attenuate increases in cerebral blood flow at the level of the germinal matrix through their effect on COX-2 and prostaglandins and assuage the inflammatory cascade that results in further disruption of the developing blood–brain barrier.¹² Additionally, steroids promote maturation of the immature choroid plexus.⁴⁵ Of note, however, a recent publication suggests that *postnatal* corticosteroids may increase the risk for neurodevelopmental difficulties with no associated reduction in risk for IVH, periventricular leukomalacia, or mortality.⁴⁶

A number of other pharmacologic agents have been evaluated for their ability to prevent IVH (► Table 12.3). Phenobarbital, which prevents fluctuations in blood pressure and is thought to mitigate free radical-mediated injury, has been extensively investigated.¹² Whitelaw and Odd performed a meta-analysis of 10 trials and found no reduction in IVH or PHH.⁴⁷ Reduction of IVH was observed serendipitously when indomethacin, a COX inhibitor, was used to close patent ductus arteriosus in newborns. Indomethacin was believed to facilitate germinal matrix vessel maturation,⁴⁸ improve cerebral autoregulation,⁴⁹ and decrease ischemia.⁵⁰ Indomethacin was investigated formally for use in preventing IVH. Although rates and severity of IVH were indeed lower with indomethacin, the effect on

long-term neurologic outcome is less clear.⁵¹ In one trial, despite a decrease in IVH, no improvement in survival or neurosensory outcome was observed.⁵² A second trial demonstrated benefit in decreasing IVH rates and severity and increasing neurodevelopmental test performance in males only. Fowlie et al recently published an update of their meta-analysis of the effect of indomethacin on IVH.⁵³ The COX inhibitor ibuprofen has a mechanism of action similar to that of indomethacin and appears to improve cerebral autoregulation in animals. In clinical trials, however, ibuprofen was ineffective in reducing IVH.⁵⁴

Other pharmacologic agents evaluated for the prevention of IVH include vitamin E, ethamsylate, and pancuronium (Pavulon). Through different mechanisms, each has been shown to decrease the incidence of IVH, but not mortality or neurologic impairments (reviewed by McCrea and Ment).¹²

12.5.2 Therapeutic Removal of Cerebrospinal Fluid via Lumbar Puncture for Post-Hemorrhagic Hydrocephalus

The efficacy of serial lumbar punctures for the treatment of PHH has been investigated extensively and also has been reviewed as part of the Cochrane Library.⁵⁵ Kruesser et al (1985) initially reported using lumbar punctures (optimally 10 mL/kg per lumbar puncture) to decrease ventricular size in patients with post-hemorrhagic ventricular dilatation.⁵⁶ A number of studies followed, including four prospective clinical trials, to investigate the effect of CSF removal on survival, hydrocephalus and requirement for a VP shunt, and neurodevelopmental outcome. Evaluating these data is difficult because of considerable variation in the subject enrollment criteria, the interventions themselves (some used lumbar punctures, some used ventricular tapping; the volume of CSF removed was inconsistent and often insufficient), and imprecision in the description of neurodevelopmental outcomes. However, meta-analysis of the available data failed to show a significant benefit of CSF removal in reducing the need for shunt surgery or neurologic disability.⁵⁵ Nonetheless, lumbar punctures continue to be used clinically in infants showing obvious signs of increased ICP or as a temporizing measure in infants about to undergo placement of a ventricular access device. In such scenarios, 10 to 20 mL/kg is typically removed to decrease ICP; however, fibrosis or other factors often reduce the volume of CSF that can be removed.

12.5.3 External Ventricular Drainage

Concurrent with studies evaluating lumbar punctures for PHH, external ventricular drainage (EVD) was proposed as a method for the continuous management of hydrocephalus and control of ICP. One series reported on 37 infants with PHH treated with EVD for a mean of 21 days. Of these, 68% required VP shunts, but 67% had normal cognitive function and 33% had normal motor function.⁵⁷ Although EVD continues to be used at some centers,⁵⁸ this method has not reached widespread acceptance for the management of PHH, presumably because of the risk for infection and technical concerns regarding the integrity of the scalp in the preterm infant. The latter concern was recently addressed in a technical report in which a modified umbilical vessel catheter was used as an EVD in this setting.⁵⁹

12.5.4 Diuretics

Because of the discouraging results from the studies investigating CSF removal described above, efforts were refocused on the pharmacologic treatment of post-hemorrhagic ventricular dilatation. Diuretics were utilized because of their potential to reduce CSF production.²⁷ Early studies investigating acetazolamide, an agent already in use for this purpose in idiopathic intracranial hypertension, reported encouraging results⁶⁰; however, a large multicenter randomized controlled trial utilizing acetazolamide and furosemide for post-hemorrhagic ventricular dilatation demonstrated no benefit to using these agents in terms of survival or need for shunt surgery in post-hemorrhagic ventricular dilatation.⁶¹ Furthermore, diuretic therapy was associated with marginally worse motor outcomes at 1 year and nephrocalcinosis. Ultimately, a Cochrane Library meta-analysis showed that diuretic use was neither safe nor effective in the treatment of PHH.⁶⁰

12.5.5 The DRIFT Trial: Early and Late Outcomes

The concept of DRIFT (*drainage, irrigation, and fibrinolytic therapy*) grew out the belief that the optimal treatment of post-hemorrhagic ventricular dilatation would not just reduce ICP but would also eliminate injurious intraventricular blood and blood breakdown products (e.g., iron) and proinflammatory cytokines. The DRIFT treatment involved placement of right frontal and left occipital ventricular catheters and then injection of low-dose tissue plasminogen activator, which was left in the ventricle for 8 hours. After the 8-hour interval, artificial CSF was continuously infused through the right frontal catheter, with egress of the fluid through the left occipital catheter set to maintain the ICP at 7 mm Hg. The infusion was continued until the CSF cleared, usually in 3 to 7 days.⁶²

The short-term outcomes (up to 6 months of age or at hospital discharge) from this randomized controlled trial showed no reduction in shunt surgery or death in the DRIFT intervention arm. At interim analysis, the trial was stopped because of suspected treatment futility and an association of DRIFT with secondary IVH. In the long-term follow-up study, however, DRIFT was associated with a reduction in cognitive disability in

survivors; 31% of infants had severe cognitive disability in the DRIFT group versus 59% in the conventional treatment group.⁶³ These results have sparked a number of research efforts investigating optimal treatment approaches for post-hemorrhagic ventricular dilatation.

12.5.6 Temporizing Neurosurgical Procedures for Post-Hemorrhagic Hydrocephalus

Ventricular Reservoir

In infants weighing less than 2 kg, a temporary ventricular access device is often inserted for the purpose of treating PHH. Perhaps the most common type of ventricular access device, the ventricular reservoir was first described in 1983 by McComb et al.⁶⁴ Once implanted, ventricular reservoirs allow serial percutaneous access of the ventricular system. Serial taps for CSF removal are then used to treat clinical and radiographic signs of elevated ICP. In general, the volume of CSF removed is 10 mL/kg per tap (although up to 20 mL/kg is considered acceptable and safe). The volume removed and the frequency of removal are then tailored to each infant based on vital signs, physical parameters (head circumference, tenseness of the anterior fontanel, and splaying of sutures), and ventricular measures obtained from serial cranial ultrasound studies or other imaging. Others have reported using flow velocities on transcranial Doppler ultrasound to guide the appropriate timing and volume of CSF removal for PHH.⁶⁵

Ventriculosubgaleal Shunt

Ventriculosubgaleal shunts (VSGSs) are an alternative method for drainage of the CSF and treating PHH-related increases in ICP.^{66,67} A VSGS comprises a ventricular catheter connected through a right-angle device to a small segment of distal catheter that is inserted into a large subgaleal pocket. Some surgeons include an in-series reservoir to permit tapping in the event of VSGS failure or a distal slit valve to provide limited back pressure and encourage physiologic CSF absorption. VSGSs provide continuous drainage of CSF into the subgaleal space and thus, in theory, maintain the ICP within a normal range on a constant basis. VSGSs are closed systems; tapping is not required, and fluid and electrolytes are not lost. Furthermore, because tapping is not required, VSGSs offer the potential for earlier hospital discharge with close follow-up. Like reservoirs, VSGSs have very low infection rates, although this rate may vary up to 6%.⁶⁸ Of note, the life span of a VSGS is generally longer than 30 days, and after this interval, if the hydrocephalus has not resolved, the surgeon can opt to revise the VSGS (usually reopening the scarred-in subgaleal pocket) or to place a permanent VP shunt.⁶⁷

To date, no study has demonstrated an advantage of VSGSs over ventricular reservoirs. Wellons et al (2009) presented their results from a four-center retrospective review of preterm infants being treated for PHH.⁵⁸ In their series, 31 of 36 subjects (86%) initially treated with VSGSs required permanent VP shunting, compared with 61 of 88 (69%) treated with ventricular reservoirs. The difference in the shunt placement

rates was statistically significant, suggesting that infants treated with ventricular reservoirs may have a lower rate of shunt dependence. A recent study at our institution found that the rates of shunt infection, shunt revision, and need for permanent shunt placement did not differ between patients with VSGSs and those with ventricular reservoirs.⁶⁹ Consistent with the findings of Lam and Heilman, the observed rate of permanent VP shunt implantation in our series was lower in the VSGS group (66.7% vs. 75.4%, $p=0.38$), although this difference was not significant.⁷⁰ The selection of type of temporizing neurosurgical procedure (ventricular reservoir vs. VSGS) remains controversial and is the subject of an ongoing prospective clinical trial through the Hydrocephalus Clinical Research Network (Shunting Outcomes in Post-Hemorrhagic Hydrocephalus, or SOPHH).

Also controversial is the timing of intervention for PHH. At present, no evidence-based guidelines exist to inform the decision of whether or when to intervene in PHH. Two multi-institutional, retrospective studies from a cooperative Dutch neonatal network focused on early treatment of PHH with CSF removal via lumbar punctures or ventricular reservoirs. Both reports demonstrated lower rates of neurologic disability and shunt dependence if CSF removal was initiated when ventricular size reached the 97th percentile^{71,72} rather than the 97th percentile + 2 standard deviations. The first study⁷¹ included 95 infants with post-hemorrhagic ventricular dilatation, 22 of whom did not develop progressive PHH. Five of 31 infants (16%) in the early treatment group and 26 of 42 infants (62%) in the late treatment group required VP shunts.⁷¹ Moreover, the number of infants with moderate or severe handicap was lower in the early treatment group (16%) than in the late treatment group (26%). The second study showed shunt dependence rates of 27.2% and 72.7% for the early and late intervention groups, respectively.⁷² The developmental quotient was also significantly lower in the late intervention group. Of note, both of these studies used lumbar punctures almost exclusively, rather than ventricular access devices, and the authors acknowledge that lumbar punctures were frequently insufficient to achieve the standard volume of 10 mL/kg per tap. Thus, these reports may underestimate the true impact of early intervention on shunt rate and neurologic deficit. Based in large part on these data, an international, multi-institutional prospective randomized controlled trial examining early treatment of PHH is currently under way (Early versus Late Ventricular Intervention Study, or ELVIS).

Ventriculoperitoneal Shunts

Placement of a VP shunt is the permanent solution for the diversion of spinal fluid. Often, patients who have a shunt placed during their prenatal period have problems with malfunctions.⁷³ Some have shown that shunt failure can occur in up to 12.6% of cases within the first 3 months of shunt placement.⁷⁴ For these reasons, the timing for initial shunt placement has been extensively studied. Most believe that a shunt should be placed once the patient reaches a weight of approximately 2 to 2.5 kg. Some advocate that the protein level should be less than 1.5 g/L, as well.²⁷ However, the data are mixed, with

another single-institution study showing no correlation between failure rates and spinal fluid protein and glucose levels. Hemorrhage and inflammation can also complicate shunt placement in these infants and can often lead to trapped ventricles. Depending on the site of obstruction, cranial nerve findings, ataxia, and changes in vital signs may develop. These situations often require the placement of complicated shunt systems, although neuroendoscopy both at our institution and others has become an accepted treatment for patients with these complicated problems.

12.5.7 Endoscopic Third Ventriculostomy

Some have advocated the use of endoscopic third ventriculostomy (ETV) with or without choroid plexus coagulation in the treatment of PHH.⁷⁵⁻⁷⁷ Although the complication rate in experienced hands is low, the data reported thus far have not shown ETV to be particularly effective in treating PHH, with fewer than 50% of procedures being successful.^{77,78} In a recent publication, Warf and colleagues demonstrated the importance of the prepontine cistern status (i.e., scarring present in the cistern) and the predictive value of FIESTA (fast imaging employing steady-state acquisition) MR imaging in applying ETV to PHH. Four of 10 patients in this study required no further shunt surgery, and the absence of scarring within the prepontine cistern correlated with a good outcome.⁷⁵ In a paper relating success of ETV to hypoabsorption, Lipina et al were successful in 37.5% of their patients with PHH, and they found that low levels of TGF- β_1 correlated with successful ETV.⁷⁹ ETVs with or without choroid plexus coagulation may prove to be useful in selected patients; limited data exist, however, to advocate the widespread use of this procedure at this time.

12.5.8 Toward Improving the Outcome of Infants with Post-Hemorrhagic Hydrocephalus

A major shortcoming limiting efforts to improve the treatment of PHH is the lack of quantifiable metrics to inform clinical decision making. Biomarkers are emerging in various fields as valuable predictors of clinical course and therapeutic response.⁸⁰⁻⁸² In the future, protein markers in CSF, blood, or urine and non-invasive techniques such as DTI, fc MRI, and quantitative MR angiography in particular may serve as useful metrics for use in the standardization and optimization of PHH treatment.⁸³ Elevated levels of nerve growth factor (NGF), neurotrophin-3 (NT-3), vascular endothelial growth factor (VEGF), erythropoietin (EPO), and soluble FAS have been observed in pediatric hydrocephalus of various types,⁸⁴⁻⁸⁷ and TGF- β elevations have been identified in PHH.^{29,88} More recently, advanced high-throughput proteomics techniques have been used to study CSF from infants with PHH, and a number of new candidate CSF markers of PHH and PHH-related neurologic disability have been identified, including L1CAM, APP, NCAM1, and brevican.⁸⁹ Such markers may be used to complement existing ventricular measures in order to optimize the timing of therapeutic intervention

or to monitor therapeutic response. Real-time functional data also may be obtained from amplitude-integrated electroencephalographic (aEEG) monitoring of ongoing cerebral electrical activity in the preterm infant. Olischar et al (2004, 2008) have suggested that aEEG tracings demonstrate characteristic changes as ventricular dilation progresses.^{90,91} This technology is particularly compelling as it may be useful in signaling real-time physiologic changes in advance of anatomical changes of PHH observed on imaging.

Pearls

In these authors' experience:

- The likelihood of progressive hydrocephalus after IVH increases with the hemorrhage grade.
- Early and aggressive intervention in the premature infant may decrease the need for a VP shunt and/or improve neurologic outcomes.
- Shunt malfunctions are extremely common in patients with IVH.

13 The Dandy-Walker Complex and Arachnoid Cysts

Hugh J. L. Garton

13.1 Dandy-Walker Complex

The Dandy-Walker complex is a heterogeneous group of anatomically and possibly embryologically related disorders that have in common a distortion of midline cerebellar anatomy and a large posterior fossa cyst, usually in communication with the fourth ventricle. The complex often appears in conjunction with other central nervous system (CNS) abnormalities, especially agenesis of the corpus callosum. Pathologically, the enlarged posterior fossa fluid collection can expand, compressing other posterior fossa structures and producing hydrocephalus. Surgical management is usually directed at treating the hydrocephalus or the posterior fossa cyst, or both, either by cerebrospinal fluid (CSF) shunt diversion or by endoscopic techniques.

13.1.1 Anatomy and Pathogenesis

Anatomy

Three described and likely related entities, (1) Dandy-Walker cyst (DWM), (2) Dandy-Walker variant (DWV), and (3) persistent Blake pouch, have been lumped together as Dandy-Walker complex (DWC). A fourth diagnosis, mega cisterna magna, may belong, as well¹⁻⁴ (► Fig. 13.1). In addition, midline posterior fossa arachnoid cysts are frequently part of the differential diagnosis of posterior fossa cystic lesions.

Anatomically, DWM consists of a large cystic fluid collection that appears to arise out of an expanded fourth ventricle with an associated lack of the cerebellar vermis. The posterior fossa is typically enlarged, with elevation of the tentorium and the torcular herophili and associated confluence of the venous sinuses. The cerebellar hemispheres are present, although they may be compressed by the cyst, which may also compress the brainstem. The aqueduct of Sylvius is variably obstructed. Hydrocephalus is present in many, although not all, patients and may be present with or without an obstructed aqueduct.^{1,4} Radiographically, initially based on axial computed tomography (CT), DWM came to be defined as an entity in which no apparent vermis was present. DWV has been defined as the presence of some residual superior vermis in the setting of a midline posterior fossa fluid collection that appears to be in communication with the fourth ventricle through a significantly enlarged valleculla, usually with a lesser degree of expansion of the posterior fossa.^{4,5} In DWV, the cerebellar vermian remnant is rotated superoanteriorly. CSF communication between the expanded fourth ventricle and the subarachnoid space is variably present, and hydrocephalus is less common.⁶ A persistent Blake pouch has been more recently defined as a posterior fossa cyst in communication with the fourth ventricle, often through a mildly expanded valleculla. The cyst walls are sometimes visible on sagittal magnetic resonance (MR) imaging as distinct from the subarachnoid space. The inferior vermis is elevated and compressed to a degree, but its anatomical divisions as seen on a sagittal plane MRI are preserved.^{2,3} Lastly, a mega cisterna magna appears as an expansion of the subarachnoid spaces of the posterior fossa. It is distinguished anatomically

from a posterior fossa arachnoid cyst by its free communication with the rest of the subarachnoid space and the fourth ventricle. The cerebellum appears normal or anteriorly displaced, and the valleculla is only minimally or not enlarged. The inferior vermis is not focally compressed as it appears to be in a persistent Blake pouch.⁶ The reader should be aware that considerable disagreement exists regarding the precision of these definitions.⁷

Pathogenesis

The combination of cerebellar dysgenesis, a large posterior fossa cyst, and hydrocephalus was first described by Sutton in 1887.⁸ Walter Dandy and Kenneth Blackfan reported a similar case in their 1914 treatise on CSF physiology.⁹ They observed that the foramina of Luschka and Magendie appeared to be absent. Dandy and others reported case series in which the etiology of the cystic dilatation in the posterior fossa was identified as occlusion of the outflow foramina of the fourth ventricle.^{10,11}

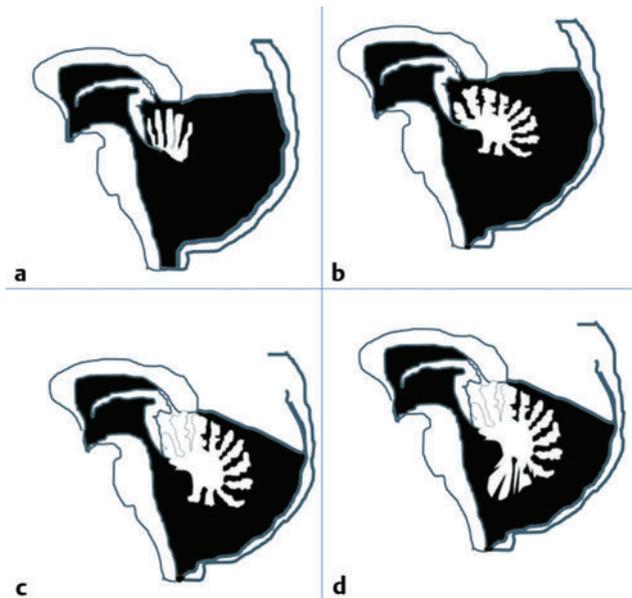

Fig. 13.1 The continuum of the Dandy-Walker complex. (a) Dandy-Walker malformation: posterior fossa enlarged, with minimal to no vermian remnant present and rotated superoanteriorly. Note: The corpus callosum is shown in this diagram for ease of understanding. However, agenesis of this structure frequently coexists with the Dandy-Walker malformation. (b) Dandy-Walker variant: posterior fossa enlarged, superior cerebellar vermis partially preserved and lobulated. (c) Persistent Blake pouch: posterior fossa volume only modestly enlarged, cerebellar vermis fully present and lobulated, inferior vermis compressed, valleculla enlarged. (d) Mega cisterna magna: posterior fossa volume modestly enlarged or normal, cerebellar vermis fully present and lobulated, valleculla normal in size. (Modified from Yildiz H, Yazici Z, Hakyemez B, Erdogan C, Parlak M., Evaluation of CSF flow patterns of posterior fossa cystic malformations using CSF flow MR imaging. *Neuroradiology* 2006;48(9):595-605.)

However, other authors identified similar cases in which the foramina of Luschka and Magendie were patent.¹² As an alternative to the hypothesis of foramina atresia, Benda proposed that maldevelopment of the cerebellar vermis was likely responsible.¹³ Supporting this, Brodal and Hauglie-Hanssen, in their seminal paper, presented two autopsy cases with detailed dissections.¹⁴ The posterior vermis was underdeveloped in both, while the more anterosuperior vermian structures were preserved. The posterior vermian remnant was noted to be continuous with the cyst lining, which had some ependymal features and which they felt was continuous with the rest of the fourth ventricular ependyma. They noted that in the human embryo, the cerebellar anlagen fuse and the vermian divisions form well before the fourth ventricular outflow foramina open. The fusion begins superiorly and proceeds inferiorly. Given the maldevelopment of the vermis seen, they argued that the primary defect must be with the precursor of this structure, the anterior membranous area (AMA).¹⁴ The appeal of this hypothesis is that it appears consistent with the variability of vermian dysgenesis seen across the DWC.

In the developing embryo, the posterior membranous area (PMA) is separated from the AMA by the developing choroid plexus. The PMA normally regresses, with the foramen of Magendie developing in its place. Tortoni-Donati et al, and later Calabrò et al, postulated that the Blake pouch, a small expansion of the PMA seen in utero, can persist and expand rather than regress to give rise to a posterior fossa fluid collection in communication with the fourth ventricle in which the inferior vermis is appropriately lobulated, if compressed.^{2,3,15} It has been further argued that the mega cisterna magna also could be categorized as a PMA developmental abnormality in which the developing PMA cyst eventually becomes connected with the subarachnoid space.^{3,15}

The reader should be aware that considerable controversy exists about whether the radiographic and clinical features occurring in DWM, DWV, and persistent Blake pouch should be considered discrete or continuous. Barkovich et al, noting the variability in radiographic findings, have argued that these entities should be viewed as a continuum.¹⁴ Geneticists and others focused on the various associated malformations seen in various aspects of DWC have argued for a more compartmentalized view.¹⁶

13.1.2 Epidemiology

In a population-based study of members of the Saudi Arabian Armed Forces and their families, DWM had an incidence of 1 in 100,000 live births.¹⁷ Long et al reported another population-based study, from northern England, wherein DWMs and DWVs were identified in utero in 1 per 11,574 live births (approximately 9 per 100,000). Most were identified on prenatal ultrasound, and 47% had associated congenital malformations. Prenatal termination, fetal demise, or neonatal demise occurred in the 43 of 47 prenatally diagnosed cases.¹⁸ Hirsch et al derived an incidence of 3 to 4 per 100,000 live births, calculating this from the incidence of hydrocephalus and the frequency of DWMs in their cohort.¹⁹ Most, although not all, studies show an increased incidence in females.^{18–21} Familial cases of DWM have been reported, but without clear inheritance patterns.^{22–24}

Reefhuis et al, using the National Birth Defects Prevention Study, noted the use of clomiphene citrate to be associated with an increased likelihood of DWMs (adjusted odds ratio [OR], 95%; confidence interval [CI], 4.44, 1.7–11.6) among a variety of other malformations, including congenital heart disease, craniosynostosis, cloacal exstrophy, and omphalocele.²⁵ Prenatal exposures to a number of other agents, including benzodiazepines and coumadin, have been reported in association with DWMs, but without sufficient power to draw conclusions.

A wide variety of genetic abnormalities have been reported in patients with DWM. Chromosome 3, specifically 3q24, which includes two genes encoding for cerebellar formation, has been implicated. Deletions of this region in animal models produce an appearance similar to DWM. Trisomy of chromosomes 9, 13, and 18 has been reported frequently in the genetic analysis of affected individuals.²⁶

13.1.3 Clinical Presentation

In neurosurgical series, the most common presentation is hydrocephalus, with rates of up to 80% of patients with DWM.^{19,20,27,28} In a population of children all with DWV, Sasaki-Adams et al reported a 29% rate of ventriculomegaly, but only 14% of the patients required surgical treatment.²¹ The incidence in nonsurgical series is likely lower. Most children present within the first year or two after birth. In many, the diagnosis is known from prenatal studies. The specifics of the presentation depend on the patient's age; infants present with progressive macrocrania, bulging fontanel, and upward gaze palsy. The speed at which patients become symptomatic is not uniform. In the series of Raimondi et al, children presented between 2 and 9 months of age.²⁹ Hirsch et al reported that 80% presented before 1 year of age, but 7 of 40 required their first treatment after 2 years of age.¹⁹ Additional symptoms may include bilateral nystagmus, alterations in speech cadence, weakness, and respiratory difficulties.²⁹ Opisthotonos has been reported, presumably due to brainstem compression.³⁰ Older patients who survive infancy and can be assessed in more detail often show a striking lack of ataxia relative to the degree of cerebellar malformation. Adult presentation has been reported with both hydrocephalus and cerebellar symptoms.^{31,32} As noted above, the majority of children born with DWMs will have associated abnormalities, which may dictate their clinical presentations. Some patients are asymptomatic and identified incidentally.³³

13.1.4 Associated Conditions

Both CNS and systemic anomalies occur in association with DWC. Depending on the setting of the study and the specifics of the malformation studied, between 50 and 80% of patients are affected. When component diagnoses of DWC are compared, malformations are very common in both DWM and DWV, and it is not yet clear whether DWV has a much lower incidence of such associated malformations, as is sometimes supposed. Has et al reported a prenatal series of 64 fetuses with DWM and 14 with DWV. Because of the setting, 45% of the parents were consanguineous. Excluding hydrocephalus, 23% (DWM) and 42% (DWV) had CNS malformations, most commonly agenesis of the corpus callosum in 10%. Non-CNS abnormalities were present in 44% and 64% of the patients with DWM and DWV,

respectively.³⁴ Sasaki-Adams reported on a group of 24 children with DWV followed over a mean 5 years, with four requiring shunt placement for hydrocephalus. Associated CNS abnormalities included agenesis of the corpus callosum (21%), schizencephaly, seizures, and cortical blindness. Non-CNS malformations were most commonly cardiac (42%) and gastrointestinal (33%).²¹ When diagnoses were made in utero, 56% of the patients with mega cisterna magna in the aforementioned population study from northern England were found to have associated anomalies, although their developmental outcome was dramatically better (25 of 29 were normal) than that for patients in this study with DWM or DWV. Given the midline nature of DWC, it is not surprising that many of the associated abnormalities are also located in the midline, including occipital encephaloceles.¹⁹ The box “Syndromes Associated with the Dandy-Walker Complex” lists a number of other neurologic abnormalities that have been noted.

- Walker-Warburg syndrome
- Yunis-Varon syndrome

DWC has been seen in a wide variety of named syndromes, which are listed above. Most of these appear in isolated case reports, but several appear with more regularity, including PHACES syndrome (posterior fossa abnormalities, hemangioma of the face, arterial abnormalities, coarctation of the aorta, eye abnormalities, sternal defects)^{35,36} Ritscher-Schinzel (3C) syndrome (cranial vault, cerebellar, cardiac)³⁷ neurocutaneous melanosis³⁸ and Meckel-Gruber syndrome (renal cystic dysplasia, CNS malformations, polydactyly, hepatic defects, pulmonary hypoplasia). In the latter, a Dandy-Walker cyst can replace the more common occipital encephalocele.^{39,40} Source: From Raimondi AJ, Sato K, Shimoki T. The Dandy-Walker Syndrome. 13.1.5 Radiology and Treatment Planning

Radiographic findings in DWC mirror the anatomical details already noted. The enlarged posterior fossa and thinned cranium can be seen on plain skull radiographs. In the normal individual, the torcular herophili lies below the lambda on skull X-rays. The vascular grooves created by the sinuses are seen below the lambdoid sutures. Lambdoid-torcular inversion occurs with the expansion of the posterior fossa seen in DWC, such that the confluence of the sinuses can lie above the lambda and is seen above the lambdoid sutures on plain X-ray. Angiographically, in the arterial phase, the posterior inferior cerebellar arteries may be absent.⁴¹ In the venous phase, the oblique course of the transverse sinuses and upward course of the straight sinus are noted.²⁹

The accuracy of prenatal ultrasound for the diagnosis of DWM/DWV has ranged in the literature from as low as 40% to up to 92%.^{18,42} Diagnosis before 18 weeks of age may have a higher error rate.¹⁸ Fetal MR imaging is increasingly being performed. Although MR imaging has significant advantages postnatally, the accuracy of prenatal diagnosis in early gestation has been questioned. Patek et al reported on 59 fetuses found on MR imaging to have posterior fossa abnormalities demonstrating the spectrum of findings seen in DWC. When the patients were assessed on postnatal imaging, for those with findings equivalent to DWV, the sensitivity was 50% (5 of 10) when the study was performed before 24 weeks, compared with 100% (9 of 9) when MR imaging was performed after 24 weeks.⁴³ Postnatally, however, MR imaging is clearly the diagnostic study of choice, revealing the posterior fossa anatomy considerably better than ultrasonography, and MR imaging is more sensitive to other CNS abnormalities seen, such as those listed in the box “Syndromes Associated with the Dandy-Walker Complex.”

When the treatment of patients with DWC is being planned, knowing which of the various fluid spaces are in communication may be helpful. The aqueduct of Sylvius may appear obviously occluded on standard MR images. However, CT after contrast injection into the ventricular system or cyst may be a more definitive study, although at the cost of radiation

exposure, usually in a young patient. As an alternative, phase-contrast MR imaging has been proposed to determine the relative patency of the cystic structures in DWC. Yildiz et al reported a very high correlation rate between phase-contrast cine MR imaging and CT cisternography in delineating the anatomy of the DWC variations and in differentiating between these and posterior fossa arachnoid cysts.⁶

13.1.6 Treatment

DWC spans a variety of clinical presentations and therefore treatment needs. DWM is associated with hydrocephalus in 80% of cases, so most patients with DWM become symptomatic and require treatment at some point in early childhood. Surgical options include CSF shunt placement, endoscopic management, and open surgical treatment. Because of the high morbidity associated with early open surgical treatments, CSF shunt placement became the principal treatment as soon as shunts were readily available.^{29,44}

The debate about whether a CSF shunt should be placed into the ventricular system, the cyst, or both has been continuing since the onset of shunt treatment and remains unresolved, save for agreement that placing the catheter into one of the spaces necessitates either preoperative demonstration of communication between the spaces or careful postoperative observation for evidence of loculation formation and noncommunication. Supporting treatment of just one compartment, Mohanty et al noted that 23 of 26 patients with DWM in their series had a patent aqueduct on MR imaging.⁴⁵ Hirsch et al reported success with isolated shunt systems in either compartment.¹⁹ However, Asai et al, reporting the Toronto Hospital for Sick Children series of 35 patients, noted that 9 of 21 patients (43%) treated with isolated ventricular shunts developed noncommunication with the cyst, necessitating cyst shunt treatment.⁴⁶ Osenbach and Menezes reported that 75% of patients with DWM had noncommunication requiring shunting of both compartments.²⁸ Naidich et al identified radiographic findings of downward herniation of the supratentorial contents after cyst decompression or lateral ventricular shunt obstruction in 25 patients with DWM.⁴⁷ Kumar et al reported that 9 of 28 patients (32%) treated with ventricular shunts required subsequent cyst shunts, compared with 6 of 7 patients (86%) with a cyst shunt who later required ventricular shunts.²⁷ Mohanty et al reported that 12 of 24 cyst shunts failed, compared with 4 of 21 ventricular shunts. Five patients went on to require shunting of both compartments, and endoscopic techniques were also used.⁴⁵ Those advocating shunt placement in both compartments have generally argued for a two-limbed shunt so that both the posterior fossa and supratentorial space are exposed to the same intracranial pressure (ICP).²⁹

A number of surgical pitfalls must be avoided during CSF shunt placement in this population. If a cyst catheter is to be placed, a lack of brain parenchyma to pass the catheter through increases the incidence of postoperative CSF leak or subcutaneous collection, with this occurring in 29% of patients with cyst shunts in one case series.⁴⁵ A very small durotomy for catheter placement, appropriately compressive dressings, and potentially an adjustable-pressure valve with a low initial setting may help limit the potential for this

complication. The enlarged posterior fossa in DWM means that the standard external landmarks for posterior ventricular shunt placement are unreliable. In addition, the dural venous anatomy is distorted, and there is risk that a bur hole intended for a supratentorial catheter may be placed over the transverse sinus. Intraoperative ultrasound can be a valuable adjunct in patients with open fontanelles to guide catheter placement. Simultaneous single-catheter placement into both the ventricular and cystic cavities has been reported with ultrasound guidance.⁴⁸ More recently, the neuroendoscopically assisted cannulation of ventricular and cyst cavities with a single catheter has been advocated.^{49,50}

Shunt failure is reported in all surgical series. In the above-cited case series, the shunt failure rates range from 4 to 60% over variable follow-up. If one compares these rates with those in similarly structured case series for other types of hydrocephalus, the results are not clearly different. Other complications include brainstem or cranial nerve injury from catheter placement, intracystic hemorrhage, and catheter migration into or out of the posterior fossa cyst.^{51,52} Chronic traction on the brainstem from a cyst catheter adherent to it, with neurologic injury, has been reported.⁵³

Endoscopic third ventriculostomy (ETV) in patients with DWM has been reported as part of larger series.^{45,54,55} Given that some patients have patent aqueducts, and assuming obstruction at the outflow of the fourth ventricle or cyst, this should be a reasonable choice. Distortion of the third ventricle and a narrow prepontine subarachnoid space increase the complexity of such procedures, but success has been reported in what would otherwise appear to be challenging cases.⁵⁶ In cases of noncommunication between the ventricles and DWM, endoscopic cyst fenestration to the ventricular system has been advocated as an addition to ETV. Mohanty et al used endoscopic techniques in addition to CSF shunt placement in 21 patients, with 5 failures (23%) requiring alternative procedures. The authors describe ETV, cyst fenestration, and guided stent placement through the superior vermian remnant from the supratentorial space.^{45,57} Warf et al reported on their experience in Uganda treating DWM/DWV with ETV and choroid plexus coagulation in 45 children who had a mean age of 5 months at treatment. With a minimum of 6 months' follow-up (mean, 24 months), 74% of the patients had not required an additional procedure. The authors observed that 39 of 41 patients had an open aqueduct as seen endoscopically at surgery.⁵⁸

Direct surgical resection of the cyst wall was the initial procedure performed before the availability of CSF shunts. It had a high failure rate and a high associated mortality rate. Summarizing nine case series reported between 1947 and 1984, Hirsch et al noted a 75% failure rate and 10% surgical mortality rate.¹⁹ However, a number of more recent publications detail, albeit in small numbers of patients, less adverse outcomes with open techniques than those in older reports.^{59,60}

13.1.7 Outcome

Survival

The analysis of outcomes for patients with DWC is complicated by the variability of the complex itself and the associated

malformations. In addition, selection and survivor biases are clearly complicating factors in addressing this question. Using the Congenital Malformations Registry of the New York State Department of Health, Salihu et al reported a 25% mortality rate by the end of the first year of life in 196 cases. The death rates were 16% for patients with isolated DWS, 32% for those with DWS and one additional organ system anomaly, and 42% for those with involvement of two or more additional organ systems.⁶¹

Intellectual Outcome

Neurodevelopmental outcomes are similarly variable. Among long-term survivors from before 1984, Hirsch et al reported that 49% had IQ scores above 90.¹⁹ A number of authors report a relationship between the degree of cerebellar dysgenesis and intellectual outcome. Gerszten and Albright reported that 45% of 120 patients with DWS had normal intelligence. Using CT images to measure the ratio of cerebellar volume to posterior fossa volume, they noted no relationship between the ratio and intellectual outcome.⁶² However, using MR imaging, Boddaert et al reported that in 21 children with DWC, those with normal cerebellar lobulation had an 82% rate of normal intelligence, whereas no child with abnormal cerebellar lobulation had normal intelligence.⁶³ Klein et al also reported a much more favorable intellectual outcome with only partial as opposed to severe vermian abnormalities.⁶⁴

With specific reference to DWV, developmental outcomes have generally been assumed to be better than those in DWM, but as in DWM, a wide range of outcomes is reported, and associated congenital anomalies appear to play a major role. Sasaki-Adams noted that 5 of 6 patients with isolated DWV had normal development, but 10 of 15 with DWV and associated abnormalities were impaired, 6 of them severely.²¹ Mega cisterna magna is generally thought of as a benign condition, and neurodevelopmental assessments in such patients support this view, with the exception that, as in other DWC entities, associated abnormalities play a significant role.^{43,65}

13.2 Arachnoid Cysts

Intracranial arachnoid cysts are arachnoid-lined expansions of the normal subarachnoid and, in some cases, intraventricular spaces. They are more common in boys than in girls, more often left-sided than right-sided, and more often above the tentorium than below it. Common sites include the middle cranial fossa, the suprasellar region, the quadrigeminal plate region, and the posterior fossa. Arachnoid cysts are usually asymptomatic, but they occasionally cause symptoms and require treatment. Treatment options include craniotomy for microsurgical cyst fenestration, endoscopic fenestration, and CSF shunt placement. The indications for treating an arachnoid cyst must be carefully considered in light of the natural history of these lesions.

13.2.1 Pathogenesis

The first clear description of an intracranial arachnoid cyst is usually credited to Richard Bright in *Reports of Medical Cases*, published in 1831. Bright identified the intra-arachnoidal location of the fluid collection and the variable size of cysts found

in different individuals. He also noted the remodeling of the brain and bone caused by the cyst. He identified most of these cysts as likely chronic, with little propensity for change.^{66,67} A variety of explanations for the origin of the arachnoid cyst have subsequently been proposed, including posttraumatic and infectious etiologies.^{68–70} Most cysts, however, likely have a congenital origin, particularly those diagnosed in childhood. Microscopically, the cyst appears as a duplicated layer of otherwise normal arachnoidal tissue that forms the cyst wall.^{68,71} In their ultrastructural study, Rengachary and Watanabe identified a split in the arachnoid membrane at the margin of the cyst, associated thickening of the collagen in the arachnoid cyst wall, hyperplasia of arachnoid cells in the cyst, and the absence of the typical spiderlike processes that define the normal arachnoid membrane. They postulated that the cysts develop in utero.⁷² The exact timing of cyst development in utero is uncertain. Studies of associated developmental venous anatomy suggest that cysts in the sylvian fissure may form in the middle of the first trimester.⁷³ Prenatal imaging has similarly demonstrated arachnoid cysts as early as the first trimester.⁷⁴ Bannister et al reported on 15 fetuses in a single-institution review. Five were diagnosed before 20 weeks. Thirteen cysts were supratentorial.⁷⁵ The authors noted that ultrasound diagnosis was sometimes difficult, with two of four aborted fetuses in this series having other etiologies accounting for the ultrasound findings. Arachnoid cysts have also been evaluated with fetal MR imaging.^{76–78} Case series of children with prenatally diagnosed arachnoid cysts report a higher incidence of associated abnormalities and the need for surgical treatment than do series of children with a postnatal diagnosis.^{75,76}

From a developmental standpoint, the predominance of a middle fossa location, the left-sided predominance, and the male predominance seen in intracranial arachnoid cysts lack a proven explanation. Wester conjectured that during the anterior growth of the temporal lobe adjacent to the frontal tissues, which creates the sylvian fissure, the leptomeningeal tissues are carried along with the cerebral lobes, so that the temporal and frontal arachnoid tissues are placed in apposition. If the developing frontal and temporal arachnoid tissues fail to fuse, cyst formation can then occur.⁷⁹ However, cysts in other locations cannot be readily explained by a similar mechanism. No clear hypothesis for the male predominance or left-sided predominance has been advanced.

Fox and Al-Mefty proposed that suprasellar arachnoid cysts form from an upward diverticulum of the membrane of Lilliequist.⁸⁰ Open or endoscopic surgical treatment of these lesions frequently discloses a much more thickened and tough membrane than is seen in middle fossa arachnoid cysts. Rests of arachnoidal tissues are periodically present in the ventricular system and are thought to account for the rare intraventricular meningioma. These cells are presumably also the source of the equally rare intraventricular arachnoid cyst.

Three theories have been advanced for how fluid accumulates in an arachnoid cyst. First, based on surgical observation, arachnoid tissues have been seen to form a one-way valve, admitting fluid during one phase of the cardiac cycle but not allowing it to subsequently escape. Second, cyst fluid may accumulate as the result of an osmotic gradient. Third, the arachnoid membranes may actively secrete the cyst contents. Schroeder and Gaab provide endoscopically acquired photographs of a slit valve in the

base of a suprasellar arachnoid cyst.^{81,82} Similar findings have been noted on cine MR imaging.⁸³ The contents of an arachnoid cyst are typically thought of as being identical to spinal fluid. However, increased cyst protein concentrations were noted in a group of 54 pediatric patients undergoing open surgical treatment.⁸⁴ The authors argued that this supported an osmotic mechanism. However, the patients did not act as their own comparators for the study, with reference CSF values being used instead. Berle et al, conversely, provided an analysis of fluid drawn from both the subarachnoid space and the arachnoid cyst in 15 patients undergoing surgical treatment. Although most electrolyte concentrations were similar, increased concentrations of phosphate, along with decreased concentrations of protein, ferritin, and lactate dehydrogenase, were noted in the cyst fluid. The authors argued that a ball-valve mechanism for filling would not allow these differences. Fluid osmolarity was similar, arguing against an osmotic force. The authors interpreted these data as supporting fluid secretion by the cyst walls or some other active transport mechanism.⁸⁵⁻⁸⁷ Earlier studies had also suggested an active transport mechanism in cyst fluid formation.⁸⁸ It is of course possible that several mechanisms may be in operation.

Trapped fluid within the arachnoid cyst displaces and distorts the adjacent neural and neurovascular structures. The degree to which neural structures tolerate the sometimes significant displacement is remarkable.⁸⁹ Even very large cysts with significant brain displacement are regularly found incidentally, particularly in the middle and anterior cranial fossae. Conversely, large midline cysts, particularly in the suprasellar region, frequently produce endocrine dysfunction and hydrocephalus.⁹⁰⁻⁹² Quadrigeminal plate arachnoid cysts are frequently associated with hydrocephalus. A variety of functional studies have addressed whether large supratentorial arachnoid cysts distort normal cerebral metabolism, with conflicting results. Wester and Hugdahl reported changes in measures of verbal laterality and handedness following surgical decompression of left temporal and frontal arachnoid cysts, with abnormal test values returning to those seen in a normal reference group after surgery.⁹³ Hund-Georgiadis et al used functional MR imaging to study language dominance and regional temporal anatomy in five right-handed patients with large left-sided arachnoid cysts. Four were left-dominant for language, despite the large ipsilat-

eral cysts, and the fifth showed mixed dominance.⁹⁴ Positron emission tomography (PET) studies in a similar group of four right-handed patients with left-sided cysts showed no right-sided language activity. However, PET/CT studies in a 51-year-old with a very large right frontal arachnoid cyst demonstrated normal cortical metabolism adjacent to the cyst, but the right cortical motor pathways were reorganized.⁸⁹ Single-photon emission computed tomography (SPECT) studies of three children with middle fossa arachnoid cysts demonstrated both local and contralateral perfusion defects that resolved after surgical intervention.⁹⁵ SPECT and cognitive improvement after surgical cyst treatment has also been reported.⁹⁶

Nonneurologic consequences of cysts have also been reported. Pressure from a cyst may thin the bone adjacent to it, rarely even to the point of incompetence, with CSF leaks occurring to the middle ear,⁹⁷ scalp⁹⁸ and nasal cavity.⁹⁹⁻¹⁰¹

13.2.2 Incidence and Epidemiology

After a review of nearly 12,000 pediatric MR imaging studies at a single institution, Al-Holou et al reported the MR imaging incidence of arachnoid cysts in children to be 2.6%. The male incidence was 3.8%, versus 1.8% for the female incidence. This male predominance persisted throughout all pediatric age ranges.¹⁰² Males also had statistically larger cysts than females on average. There was no increase in the incidence throughout childhood—that is, new cases were not detected more commonly at older ages. Middle fossa cysts accounted for 45% of all cysts and were twice as common on the left side as on the right. About one-third of cysts were located in the posterior fossa, with the majority posterior to the cerebellum and 6% in the cerebello-pontine angle (► Fig. 13.2).¹⁰² Contrasting with the findings in earlier, smaller studies, there was no gender difference between cyst sidedness.^{79,103} Earlier estimates in the literature, also from smaller samples, noted incidence rates from 0.3 to 1.7%, with the study patients mostly adults.¹⁰⁴⁻¹⁰⁶ Most incidence studies have similarly identified an increased incidence of cysts in males and a left-sided predominance, particularly for middle fossa arachnoid cysts. Using the same methodology as in the aforementioned pediatric study, Al-Holou et al reported a 1.4% adult incidence of arachnoid cysts drawn from a database of more than 48,000 MR imaging studies, with a male

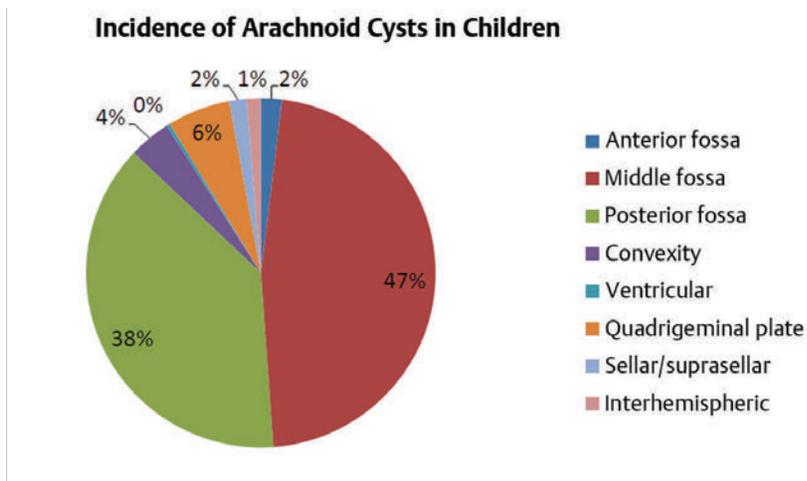

Fig. 13.2 The incidence of arachnoid cysts in 309 children drawn from a sample of 11,738 consecutive MR imaging studies. (Modified from Al-Holou WN, Yew AY, Boomsaad ZE, Garton HJ, Muraszko KM, Maher CO. Prevalence and natural history of arachnoid cysts in children. *J Neurosurg Pediatr* 2010;5 (6):578-585.)

predominance (1.8% vs. 1.1%) There was no change in incidence by age. Middle fossa cysts (34%) and retrocerebellar cysts (17%) were seen most commonly.⁹⁰

Arachnoid cysts have also been reported in multiple other sites, including within the sella turcica,^{107,108} within the ventricular system¹⁰⁸⁻¹¹⁰ and between the cerebral hemispheres.¹¹¹ Suprasellar, quadrigeminal plate, ambient cistern, cerebellopontine, and retrocerebellar arachnoid cysts are also seen.

Middle fossa cysts have been classified by Galassi et al.¹¹² Type 1 cysts are small and lens-shaped, are located at the proximal sylvian fissure, and do not produce any midline shift. Galassi et al reported that these cysts appear to fill with spinally injected contrast media. Type 2 cysts are more rectangular in shape and extend in the sylvian fissure to border the insula. Minimal midline shift may be present. Type 3 lesions involve the entire sylvian fissure, with thinning of the adjacent bone and more obvious midline shift, and they do not appear to communicate with the subarachnoid space on contrast injection. Of the middle fossa cysts in children reported by Al-Holou et al, 68% were type 1, 15% were type 2, and 17% were type 3.¹⁰² In most case series, type 1 lesions are less likely to be treated than type 2 or 3 lesions.

No clear ethnic or racial trends have been reported for arachnoid cysts. Familial occurrence has been reported.¹¹³ Arachnoid cysts have been associated with a myriad of conditions in case reports, but given their relatively common occurrence, these associations are more likely to be coincident than causal. However, two conditions are more firmly linked to arachnoid cysts. Autosomal-dominant polycystic kidney disease (ADPKD) is associated with an increased incidence of arachnoid cysts. Schievink et al reported an 8.1% incidence of arachnoid cysts in a group of 247 patients with ADPKD. There was also a higher incidence of cystic liver disease in the patients with ADPKD and arachnoid cysts than in those without. However, no patient in this series required treatment for an arachnoid cyst.¹¹⁴ Additionally, glutaric aciduria type 1 is associated with bilateral middle fossa arachnoid cysts. Patients with this disorder may be at increased risk for harm during surgical procedures.¹¹⁵⁻¹¹⁸

13.2.3 Natural History

Size

Most arachnoid cysts do not expand after initial radiographic diagnosis. In a study of 111 pediatric patients with a mean follow-up of 3.5 years and serial MR imaging, 87 cysts remained stable in size, 11 increased in size, and 13 decreased in size. Only 3 patients in this series became symptomatic. All patients whose cysts expanded were less than 4 years of age at initial diagnosis, and follow-up was similar for those younger and older than 4 years.¹⁰² Among adult patients studied by the same group, of 213 cysts followed over a mean of 3.3 years, 5 (2.3%) increased in size, while 2 (1%) decreased in size.⁹⁰ A number of other studies have identified the connection between young age at diagnosis and the possibility of cyst expansion. Rao et al reported 2 children, 4 years of age or younger, who developed symptomatic expansion. In reviewing the pediatric literature to 2005, they identified 3 additional cases of radiographically documented symptomatic expansion in children who, they reported, were ages 8 months, 7 years, and 6 months.^{119,120} Radiographic resolution has also been documented on follow-up imaging.¹²¹⁻¹²³

Intracystic Hemorrhage and Subdural Hygroma

Rarely, arachnoid cysts may rupture and present with a subdural CSF fluid collection. This is often associated with either modest or more dramatic subdural hemorrhage, presumably from the tearing of bridging veins associated with the cyst wall. Rupture has been reported to occur both after trauma and spontaneously.¹²⁴⁻¹²⁶ Radiographic resolution has been reported after rupture¹²⁷ and has been seen in the author's practice even without surgical intervention. Cress et al reported hemorrhage in 14 of 232 patients (6%) identified through an imaging database at a single institution. Using a case-control methodology, matching the patients for age, sex, side, and anatomical location with patients who had unruptured arachnoid cysts, the authors noted that children with rupture at presentation were more likely to have symptoms of intracranial hypertension and to have midline shift associated with their cysts. Cyst size larger than 5 cm in any dimension and prior head injury within 30 days were seen with statistically much greater frequency in the cohort with rupture, but altitude of residence was not different. Of the 14 patients with rupture, 10 were managed surgically. All patients recovered fully, but 14% required permanent CSF shunt placement.¹²⁸ Other studies have reported a lower incidence of hemorrhage. Al-Holou et al reported 1 patient presenting with hemorrhage among 309 children (0.3%) with arachnoid cysts identified on MR imaging.¹⁰² Wester and Heland reported 11 of 246 adult and pediatric patients (4.6%) presenting with hemorrhage. All 11 patients underwent surgical treatment and recovered without postoperative morbidity. In this later study, cyst size was not noted to be a risk factor.¹²⁹ Parsch et al, in a largely adult series, noted that 2 of 96 incidentally identified arachnoid cysts drawn from 11,487 imaged patients presented with hemorrhage.¹³⁰

13.2.4 Clinical Presentation

Many arachnoid cysts are diagnosed incidentally when MR imaging is performed for an indication likely to be unrelated to their presence. In the University of Michigan pediatric series, only 6.8% of patients with radiographically identified arachnoid cysts were felt to be symptomatic.¹⁰² However, among the patients deemed symptomatic, the clinical manifestations related either to generalized increased ICP or to focal symptoms resulting from displacement or compression of specific structures by the arachnoid cyst. In symptomatic infants, there is often associated hydrocephalus, and the presentation of progressive macrocephaly, split sutures, and a Parinaud syndrome can occur. In older children, headaches, nausea and vomiting, lethargy, sixth nerve palsy, and papilledema can all occur. In the middle fossa, a cyst can cause focal prominence of the overlying bone and distortion of the adjacent orbit with proptosis. Suprasellar arachnoid cysts can produce endocrinopathy related to deformity of the pituitary axis and visual disturbance from displacement of the optic apparatus. Quadrigeminal plate arachnoid cysts most frequently produce hydrocephalus but may cause a Parinaud syndrome from local deformation of the tectum. Cerebellopontine angle cysts have been associated with nystagmus, facial weakness, hearing loss, and tinnitus.¹³¹ Given the above descriptions, the clinician is faced with the task of determining,

for an individual patient, whether there is a causal relationship between reported complaints and the identified cyst. Information regarding the sensitivity and specificity of common features obtained from the history and physical examination for predicting the potential for future harm or a positive response to treatment is not widely available. This is especially true for common protean symptoms like headache.

Headaches

In most pediatric series of symptomatic patients, headaches are among the most common presenting symptoms.^{102,132-138} The headaches that are associated with arachnoid cysts in the absence of overt hydrocephalus have not been specifically characterized in the literature. Unlike in other neurosurgical conditions, such as Chiari 1 malformation, in which there appears to be a correlation between the specifics of the headache and the likelihood of response to surgical therapy, no similar specificity has been demonstrated for arachnoid cysts. One can speculate that the pain arises from dural compression or displacement of the dura, given its rich sensory innervation, although focal episodic pain is more likely to be migrainous in an otherwise neurologically normal child. However, why some patients with cysts that cause mass effect on adjacent bone or midline shift have headaches and others do not is not known. One study has looked at the relationship between intracranial hypertension, cyst size, and clinical symptoms. Di Rocco et al reported on 11 children with middle fossa arachnoid cysts who underwent ICP monitoring. The ICP was observed to be normal (< 10 mm Hg, author's definition) in 3 children with smaller, Galassi type 1 cysts, although 2 of these 3 had headaches. Of 7 patients who had larger, Galassi type 2 cysts, none had headaches. Half of these children had ICPs more consistently about 10 mm Hg, half had ICPs below. Two patients with larger, type 3 cysts had significant ICP elevations, one with headache.¹³⁹ Migraine headaches in children are common, with a prevalence of 2.7 to 10.6%¹⁴⁰ Given that arachnoid cysts are also relatively common, a significant number of children will present with both entities as a matter of chance.

Epilepsy

In surgical series, seizures occur in 20 to 34% of patients with arachnoid cysts.^{132,134,136} However, this is almost certainly a selection bias, because the incidence in nonsurgical series is considerably lower. In the previously noted MR imaging study of the incidence of arachnoid cysts, Al-Holou et al reported that there was a concern for seizures in 16% of children undergoing MR imaging studies in whom an arachnoid cyst was present.¹⁰² Presumably, the actual incidence of epilepsy was lower. The relationship between arachnoid cysts and seizures is not straightforward. Although one might postulate a global effect of an arachnoid cyst, increasing the propensity for epilepsy, it is more likely that the effect of the cyst would be felt most on the adjacent tissue. A majority of arachnoid cysts present in the temporal fossa. The temporal lobe is more prone to epilepsy than other regions of the brain. So it might be expected that complex partial epilepsy would be the most common type in patients with arachnoid cysts. Arroyo and Santamaria identified a 2% incidence of arachnoid cysts in a clinic for adults with refractory

epilepsy. However, only 3 of 12 patients with middle fossa cysts had temporal lobe epilepsy. Interestingly, about 25% of the patients with arachnoid cysts in this series were found to have cortical dysplasias remote from the arachnoid cyst.¹⁴¹ Similarly, Yalçın reported seizure diagnoses in 21 patients with arachnoid cysts, mostly in the middle fossa, drawn from a clinical population of 612. Eleven patients had generalized seizures, and 5 had focal nontemporal epilepsy. Four patients had temporal complex partial events, but of these, only one had an ipsilateral cyst.¹⁴² Arai et al assessed with preoperative electroencephalography (EEG) 77 patients with middle fossa arachnoid cysts, who were subsequently treated with cyst-peritoneal shunt placement; 54% had EEG abnormalities and 34% had documented seizures, of whom 16 had generalized seizures, 8 had simple partial seizures, and 2 had complex partial seizures. After shunt treatment with a high rate of cyst decompression, 71% of the observed postoperative EEGs were either unchanged or worse. Of 26 patients, 21 required ongoing medical therapy for seizures, 1 had resolution of the epilepsy, and 4 required significant additional medications or alternative surgery or died as a result of their epilepsy.¹³³ Conversely, multiple surgical series, reviewed below, do show considerable improvements in seizure outcomes, more strongly implying a causal connection.

Developmental Delay and Cognitive Deficits

Surgical series report cognitive disorders and developmental delay in up to a 25% of patients undergoing treatment.¹³² In some cases, these are believed to be due to the arachnoid cyst.¹⁴³ As noted previously, pediatric patients with arachnoid cysts have been demonstrated to have abnormal SPECT studies^{95,144} and PET/CT studies in the brain adjacent to the arachnoid cyst.¹⁴⁵ Neuropsychometric testing in 55 adults conducted pre- and postoperatively and compared with testing in a group of healthy volunteers demonstrated both significantly worse performance at baseline and postoperative improvement in measures of visual retention and of attention and interference, among other parameters tested.¹⁴⁶ Similar improvements in verbal memory in adult patients after cyst decompression have been reported by the same group.¹⁴⁷ However, pediatric case series consistently report little improvement in cognitive delay in patients undergoing cyst decompression, even when other symptoms, such as ICP-related headaches and progressive macrocephaly, are improved.^{133,134}

Suprasellar Cysts and Neuroendocrinologic Disturbances

Suprasellar cysts and large middle fossa cysts that encroach on the hypothalamic-pituitary axis unsurprisingly can produce significant endocrinologic disturbances. Central precocious puberty, inadequate growth hormone production, hypothyroidism, amenorrhea, low plasma testosterone, diabetes insipidus, and the syndrome of inappropriate antidiuretic hormone secretion have all been reported.^{91,92,148,149} Endocrinopathy is frequent enough in patients with suprasellar cysts to recommend screening for all such patients.

The bobble-head doll syndrome, a movement disorder characterized by head bobbing in both the sagittal and coronal planes, usually at a frequency of 2 to 3 Hz, is associated with

lesions of the hypothalamus and third ventricle. It has also been reported with suprasellar arachnoid cysts.^{150–152} In these case reports, cyst treatment is associated with resolution of the symptoms. El-Ghandour, reporting a case series of 25 children with suprasellar arachnoid cysts, noted that all had hydrocephalus, 5 had developmental delay, 1 had visual impairment, and 1 had precocious puberty. Two patients had the aforementioned bobble-head doll syndrome.¹⁵¹

Intrasellar arachnoid cysts have also been reported but are rarely diagnosed in children.¹⁵³

Cerebellopontine Angle Cysts

Cerebellopontine angle arachnoid cysts account for about 15% of all cysts identified in children.^{90,138} In adult patients, cerebellopontine angle cysts are more likely to be symptomatic than arachnoid cysts generally, but this is not clearly so in children.^{90,102} Symptoms reported in children include headaches, vomiting, facial weakness, hearing loss, tinnitus, and ataxia.¹³¹

13.2.5 Radiology

CT and particularly MR imaging are the principal radiographic tools for diagnosis. Although MR imaging is likely the more useful, CT studies can still play an important role in sorting through the differential diagnoses of arachnoid cysts in certain locations and can be an important tool in identifying the rare coincident intracystic or subdural hemorrhage. On CT, cysts without hemorrhage should be identical in density to CSF. MR imaging sequences also can help to demonstrate subdural hematoma in arachnoid cysts.¹⁵⁴ A pitfall is that fat is similar enough in intensity to CSF on CT scans that certain lesions, such as cerebellopontine angle dermoid or epidermoid cysts, cannot be readily distinguished. For this latter diagnosis, even standard T1- and T2-weighted MR imaging may not be helpful. Diffusion-weighted images, however, readily differentiate the hyperintense dermoid cyst from the hypointense arachnoid cyst and should be part of the evaluation of intracranial cystic lesions.¹⁵⁵ Conversely, CT can be very helpful in identifying calcium in suprasellar lesions, which is sometimes hard to discern on MR imaging sequences. Calcium in a cyst wall makes it much more likely for a lesion to be a craniopharyngioma than a suprasellar arachnoid cyst.

With the exception of cysts in the intraventricular location, MR imaging studies should demonstrate that the arachnoid cyst is extra-axial. Particularly, there should be a gray matter boundary to the cyst on the brain side. The author has cared for a child referred with the diagnosis of an expanding arachnoid cyst. On inspection, the lesion proved to have a white matter boundary and was instead an expanding tumor cyst. ▶ Table 13.1 lists entities in the radiographic differential diagnosis by anatomical location.

Suprasellar arachnoid cysts frequently produce hydrocephalus via obstruction at the level of the foramen of Monro. The third ventricle is compressed and displaced posteriorly. However, because the cyst itself is of CSF intensity, on axial imaging, particularly with CT, it can be mistaken for the third ventricle, leading to a mistaken impression of an aqueductal obstruction. In axial imaging, the foramen of Monro is

typically bowed anterolaterally by the expanding extra-axial suprasellar arachnoid cyst. Sagittal plain imaging is usually diagnostic (▶ Fig. 13.3).

CT cisternography can demonstrate the relative communication of arachnoid cysts with the remainder of the subarachnoid space. The Galassi classification is in part defined by the penetration of subarachnoid contrast.¹¹² However, in practice, cisternography is not commonly used in supratentorial lesions. Conversely, differentiating posterior fossa cystic lesions can be very challenging. The reader is referred to the prior section on DWC. Here, CT cisternography may play an important role. However, more recently, phase-contrast MR imaging has been reported to differentiate CSF communication in both posterior fossa and supratentorial arachnoid cysts.^{6,156}

As noted previously, arachnoid cysts are a common incidental lesion. Once they are diagnosed, there may be a desire for further radiographic follow-up. Cysts can expand; however, as has been discussed earlier, among asymptomatic patients more than 4 years of age, this appears to be uncommon.¹⁰²

13.2.6 Treatment

Indications

Because arachnoid cysts are common, with the finding incidental and many of the symptoms protean, very careful patient selection is warranted to avoid overtreatment. Small, asymptomatic cysts can readily be observed and, in older patients, may

not require even follow-up imaging. Conversely, patients with clear symptoms of increased ICP that correlate with cyst expansion, such as progressive macrocephaly, papilledema, and progressive cranial neuropathy, are candidates for surgical intervention. A third group with more equivocal symptoms presents the most difficulty. This group includes patients with larger cysts and chronic headaches, but without an ICP-related component, perhaps with migraine features instead. It also includes patients with a seizure disorder that does not precisely localize to the brain adjacent to the cyst. Other situations in this category include static developmental delay and static neurologic symptoms potentially related by location to a cyst, such as static hearing loss associated with an ipsilateral, stable cerebellopontine angle cyst. The treatment of patients in this group is by no means unreported; however, further study and/or observation has also been advocated.¹⁵⁷ Lastly, a group of children will present with large or even very large cysts after an incidental diagnosis and be found to be asymptomatic. Treatment in this group is also controversial, with proposed benefits of reduction in hemorrhage risk and improvement in unrecognized neurocognitive deficits to be balanced against the not insignificant risk for complications.

With specific reference to Galassi type 2 arachnoid cysts, Tamburrini et al surveyed 60 senior pediatric neurosurgeons from Europe, North and South America, and the Near and Far East, presenting a varying clinical scenario to elicit opinions on management. The proposed patient was a 2.7-year-old boy with a left middle fossa type 2 arachnoid cyst. When an asymptomatic, incidental diagnosis was presented, 82% of the participants indicated that they would not recommend surgical intervention; most felt that a follow-up clinic visit and/or MR imaging was indicated. Of the remaining 17%, 13.3% recommended operative intervention to reduce the perceived long-term risk for intracranial hemorrhage. Of the group, 26.5% recommended the avoidance of contact sports in this setting. When the scenario was changed to a potentially symptomatic diagnosis of chronic headaches, about one-third of the respondents recommended surgery without further evaluation, 24% recommended further clinical and/or radiographic follow-up, and the remainder recommended additional study, such as ICP monitoring or dynamic MR imaging. It should be noted that the example patient (2.7 years old) is younger than most patients diagnosed

with a chronic headache syndrome, possibly influencing the survey results. When seizures were considered as the primary presenting complaint, fully a quarter of the respondents recommended surgery, although most did so because of a perceived benefit to avoiding intracranial hemorrhage in a patient prone to head trauma because of the seizures. When a lateralizing EEG was provided, 50% of the respondents said that they would recommend a surgical procedure.¹⁵⁸ It should be noted that opinion surveys like this one are not strong evidence upon which to formulate practice guidelines, but the study does give a good idea of the state of treatment opinion at the time of publication. There are no randomized trials comparing treatment with nontreatment for arachnoid cysts for any of the above indications as of early 2013.

As noted in a previous section, the incidence of intracranial hemorrhage in patients with arachnoid cysts has been reported to be from 0.3 to 6%.^{102,128} Also as noted above, recommendations for prophylactic surgical treatment to avoid the risk for hemorrhage are not uncommon. However, a number of case series report an ongoing risk for intracranial hemorrhage, even after treatment. Spacca et al reported 4 symptomatic late subdural hemorrhages after trauma in a series of 40 patients undergoing endoscopic treatment for middle fossa arachnoid cysts.¹³⁵ In a microsurgical series, Levy et al reported 2 children who required surgical intervention for delayed subdural hemorrhage among 50 treated.¹³⁶ In these series, the rates of hemorrhage from trauma despite treatment (4 to 10%) do not appear to be greatly different from the natural history of the disease. Other series do not report cases of postoperative intracranial hemorrhage after trauma.^{132,159}

Assuming that surgical treatment is indicated, the options include open surgical fenestration,^{159–162} cyst–peritoneal shunt placement,^{79,133,134,138,162} and most recently endoscopic cyst fenestration.^{135,137,162–166}

Surgical Fenestration with Open Microsurgery

The advantages of open surgical fenestration are excellent surgical visualization, a potentially lower risk for intraoperative complications in comparison with endoscopic techniques, and

the use of native CSF pathways rather than permanent shunt hardware. For smaller cysts in eloquent locations, such as the cerebellopontine angle, open surgical fenestration may be the ideal choice. Levy et al described a microsurgical approach to middle fossa arachnoid cysts in which a small temporal craniotomy and extensive sharp microdissection of the basal cisterns were used to expose the internal carotid artery and optic nerve, with fenestration of the arachnoid between the two. The posterior communicating artery and cranial nerve III were exposed, and the membrane of Lilliequist was opened to expose the basilar artery. The authors advised against extensively stripping membranes from the temporal lobe surface.¹³⁶ Helland and Wester reported on 48 patients, 83% treated surgically for presenting complaints of headaches (31%), impaired cognition (27%), and/or seizures (21%). At follow-up, 82% had improved symptomatically while 14% had no improvement and 2 of the 48 worsened clinically despite improved images. On postoperative imaging, 79% of the cysts had resolved or were less than 50% of their baseline size. Self-reported function improved in 67% of patients. Complications were reported as follows: subdural fluid collections in 2 patients, hydrocephalus in 1 patient. The degree of cyst size reduction appeared to correlate with the degree of clinical improvement. The issue of volume reduction versus symptomatic improvement was also addressed by these authors in a series of adult patients, in whom volume reduction did not clearly correlate with outcome.^{118,132} Other comparative series, including the European Cooperative Study, have supported a correlation between cyst size reduction and clinical outcome.¹⁶⁷⁻¹⁶⁹

Levy et al reported on 50 children treated with microsurgical fenestration with a mean follow-up of 3 years. About half of those presenting with epilepsy improved, compared with 67% of those with headaches. A few patients presented with behavioral abnormalities and did not improve. Hypothalamic disturbances improved in about half of the cases. Focal neurologic symptoms, such as sixth nerve palsy and hemiparesis, improved reliably. After surgery, 82% of the cysts decreased in size with treatment, but none completely resolved. Ten percent of patients developed a pseudomeningocele, but this could be managed conservatively. A 6% CSF leak rate was reported. In follow-up, 8% were treated with a CSF shunt for persistent symptoms.¹³⁶

These optimistic reports for open surgery can be contrasted with those of Ciricillo et al, from the University of California, San Francisco, who reported a series of 40 children. Fifteen were treated with fenestration, and two-thirds of these showed no clinical or radiographic improvement and were converted to CSF shunt placement. Of 20 patients initially treated with CSF shunt, 6 required 9 shunt revisions over a median 8-year follow-up.¹³⁴ The authors reported complications of the fenestration procedure that included aseptic meningitis, seizures, cranial nerve III palsy, and subdural hematoma. Complications occurring in patients undergoing shunt placement included protracted nausea and vomiting (6 of 20 patients), aseptic meningitis, and transient cranial nerve VI palsy, believed to be related to ICP changes.¹³⁴

Fewel et al, from the University of California, Los Angeles, reported on 102 patients treated over 20 years. Seventy-three percent of the children treated with open fenestration who did not have associated hydrocephalus at presentation required no

further treatment over the follow-up interval. However, only about one-third of the patients presenting with concomitant arachnoid cysts and hydrocephalus were successfully treated with initial fenestration. The authors recommended combined ventriculoperitoneal shunt placement and cyst fenestration when hydrocephalus was present.¹⁵⁹ Holst et al reported a series of 69 patients treated from 1997 to 2007, comparing all three treatments in a mixed series. Relapse rates after microsurgery were lower (28%) than with shunt treatment (36%) or endoscopy (73%).¹⁶²

Cyst-Peritoneal Shunt

CSF shunt placement has the advantage of being surgically straightforward, with limited blood loss. However, it has the potential disadvantage of exposing the patient to the long-term risk of shunt dependence, although as noted below, a number of authors have reported delayed removal of the cyst shunt after cyst decompression. Although all the techniques report a significant degree of cyst decompression, it is likely that CSF shunt treatment, because of the ability to induce low ICP, offers the opportunity of maximum cyst decompression in comparison with the other techniques. (► Fig. 13.4) Whether this is valuable for outcomes is debated. Arai et al reported on 77 patients who included both adults and children but whose mean age was 12 years. Trepine-size craniotomies were performed, and reachable portions of the outer membrane of the arachnoid cyst were removed. Low-pressure shunts were used without an antisiphon system. Over a mean of 7.7 years, there was marked expansion of the brain, with near-oblivation of even Galassi type 3 cysts. Although symptoms of intracranial hypertension such as headaches and papilledema improved, preoperative cognitive delays did not reliably improve despite resolution of the cysts by imaging. Complications occurred in 11 patients, with 8 patients requiring 13 shunt revisions over a mean 7-year follow-up. An important observation was that at least half of the 8 patients presented with acute symptoms and signs of intracranial hypertension at the time of shunt failure, even though the cyst size was not noted to increase significantly.¹³³ The author has observed a similar phenomenon in his practice. Alexiou et al reported on 89 children undergoing CSF shunt

Fig. 13.4 Anterior fossa arachnoid cysts showing significant resolution after cerebrospinal fluid shunt placement.

treatment for intracranial arachnoid cysts. With 4 patients lost to follow-up, all remaining patients had resolution of their presenting symptoms. Cyst size was reduced in all patients, and to a greater degree in those less than 2 years of age at shunt placement. Thirty-four patients (39%) required shunt revision, 13 of them more than once. Shunt infections occurred in 8.7%. Two patients had a subdural hematoma, and one patient had an intracranial/intracystic hemorrhage after trauma despite shunt placement.¹³⁸

Shim and colleagues reported their experience treating 181 pediatric patients with all three techniques. For middle fossa cysts, shunt placement had the highest rate of obliteration of the cyst but led to shunt dependence, in some cases with shunt failure and increased ICP, without significant change in ventricular size; open and endoscopic techniques were not associated with these complications. However, shunt removal was possible in 8 of 11 patients.¹⁶⁶

Complications of shunt placement in patients with arachnoid cysts appear to mirror those in the general population of patients with hydrocephalus.

Endoscopic Cyst Fenestration

Endoscopic fenestration offers the advantages of shunt avoidance and causes less external tissue disruption in comparison with open surgical techniques. Disadvantages include difficulties with visualizing and controlling hemorrhage and potentially a more limited fenestration, although it has been noted that with the use of angled endoscope lenses, the endoscopic visualization can in some cases exceed what can be achieved with the microscope.¹³⁷ Spacca et al reported on 40 children treated endoscopically from 2001 to 2007. The surgical technique involved stereotactic localization of the operative corridor and fenestration of the optic–carotid and oculomotor triangles. Resolution or improvement of the presenting symptoms occurred in patients with headaches (92%), macrocrania (100%), and focal neurologic deficits (75%). However, developmental delay did not improve in any of the 6 patients who presented with this problem. At a mean follow-up of 27 months, 60% showed a reduction in cyst size. Complications included subdural hygroma in 5 of 30 patients and meningitis in 1 patient.¹³⁵ The use of stereotactic navigation is supported by some^{164,170} but not all authors.¹⁷¹ Turhan et al compared microsurgery with endoscopic treatments for middle fossa arachnoid cysts in a single institution. The groups were unbalanced with respect to cyst size, with more grade 3 lesions treated endoscopically. Imaging follow-up at 1 year disclosed a reduction in cyst size by at least one Galassi grade in all but 2 patients. Complications, most commonly subdural hygroma, were more frequent in the endoscopic group (47%) than in the microsurgical patients (23%).¹³⁷ Mottolese et al reported on 35 children treated with simultaneous shunt placement with an adjustable valve and endoscopic cyst fenestration. In 60%, the cysts disappeared entirely, and in half the shunt could later be removed.¹⁷²

Shunting of arachnoid cysts to the ventricular system^{173,174} and subdural space¹⁷⁵ is also reported. This technique has the theoretical advantage of a more physiologic drainage than shunt placement to an extracerebral cavity, but experience is limited.

Treatment of Suprasellar Arachnoid Cysts

Because of their location, suprasellar cysts more frequently produce hydrocephalus and are more likely to require treatment. Open microsurgery has been reported via subfrontal, pterional, transventricular, and transcallosal routes.¹⁷⁶ Hoffman et al advocated a transcallosal approach because it allowed the cyst to communicate with both the ventricular system and the subarachnoid space, whereas with subfrontal and pterional routes, ventricular entry was difficult.¹⁷⁷ However, the presence of hydrocephalus provides an avenue for endoscopic techniques, which are considerably less invasive. Shunt treatment of the hydrocephalus in this situation without addressing the arachnoid cyst can, unsurprisingly, lead to cyst expansion.¹⁷⁸ As viewed endoscopically, the suprasellar arachnoid cyst wall is often very tough, making direct, unassisted cannulation difficult.¹⁵¹ Stereotactic, radiographic, or endoscopic assistance improves the safety and success of the procedure. Endoscopic procedures allow fenestration of the arachnoid cyst to the ventricular system and fenestration of the cyst to the subarachnoid space from the same approach. Ogiwara et al reported a small series of 6 children treated endoscopically between 2004 and 2011. The main presenting complaint was progressive macrocephaly. In 3 of the 6, cisternal–subarachnoid communication was noted on cisternography. Patients underwent either ventriculocystostomy (VC) or ventriculocystocisternostomy (VCC), with 5 of the 6 experiencing resolution of their presenting complaints and 1 requiring CSF shunt placement.¹⁷⁹ El-Ghandour compared VC with VCC in 25 patients. Treatment with either approach resulted in the resolution of macrocrania and intracranial hypertension in all patients, and in improvements in developmental delay in roughly half. Cyst size reduction was more apparent with VCC than with VC (100% vs. 81%). At a mean follow-up of 4.6 years, recurrence was noted in 27% of the VC patients versus none of the VCC patients.¹⁵¹

Arachnoid cysts of the sella turcica have been successfully managed by a transsphenoidal route with the use of both open and endoscopic techniques.¹⁵³

Treatment of Quadrigeminal and Posterior Fossa Arachnoid Cysts

Quadrigeminal arachnoid cysts are most frequently reported to be approached endoscopically in recently published series.^{180–182} Because these cysts present with a very high incidence of hydrocephalus from posterior third ventricular obstruction, fenestration procedures are often combined with either ETV or CSF shunt placement. A coronal bur hole is used, with the arachnoid cyst seen bulging into the ventricular wall. After fenestration of the cyst to the lateral ventricle, the trajectory allows an ETV to be performed with the same bur hole. Erşahin and Kesikçi treated 17 patients in this fashion. They noted that among patients treated at 6 months of age or younger, a CSF shunt was generally required because of ETV failure, but in only one case did the arachnoid cyst itself require re-treatment. Presenting symptoms of intracranial hypertension and progressive macrocephaly were alleviated in all patients. Infants in this series had severe hydrocephalus at presentation, and 3 developed overdrainage complications that required subdural shunt placement in 2 patients.¹⁸² A second recent report is quite similar.¹⁸¹

Interestingly, despite the location of their cysts, none of the patients in either of these series presented with a defined endocrinopathy. Many patients presenting with endocrinopathy will require exogenous hormone replacement for normal growth and development.¹⁸³

Patients with posterior fossa arachnoid cysts, particularly those in the cerebellopontine angle, are appropriate candidates for open fenestration, given the smaller working space and the proximity of cranial nerves and vascular structures. Shunt placement likely carries with it a higher risk for cranial nerve injury. Jallo et al reported successful open fenestration in 5 children, 3 of whom presented with generalized symptoms of intracranial hypertension and 2 of whom had brainstem and cerebellar symptoms. Following treatment, the generalized symptoms improved, but the cranial neuropathies did not.¹³¹ A pediatric case report of successful endoscopic fenestration of the cerebellopontine angle, with improvement in presenting symptoms of hearing loss and facial weakness, has now appeared.¹⁸⁰

Technique Selection

Among the various surgical techniques, major differences in the likelihood of resolution of the symptoms are not clearly apparent. The choice between them depends, therefore, on complication management, individual surgeon experience, and perhaps long-term goals. For middle fossa cysts in older children, in whom dramatic brain expansion may not be the goal, cyst fenestration by either open or endoscopic technique would appear to be preferable to the long-term risk for shunt dependence. Cyst shunting can be used in cases of fenestration failure. For younger children with much larger cysts, in whom the goal may be brain expansion, this is likely to be more completely accomplished with CSF shunt placement. Whether the hoped-for gains to be achieved by brain expansion in this setting are realistic is still unclear and perhaps not well supported by the available evidence. For patients with suprasellar or quadrigeminal plate arachnoid cysts, an endoscopic approach is likely preferable, although it appears that many infants will need a combination of both endoscopic surgery and cyst shunt placement. Posterior fossa cysts, particularly those in the cerebellopontine angle, are likely better treated in an open fashion.

13.2.7 Outcomes

The natural history and surgical outcomes have been presented individually above. However, to summarize, there is strong evidence that most arachnoid cysts are asymptomatic, rarely expand, and infrequently hemorrhage. In carefully selected symptomatic patients, surgical management appears to be highly successful in resolving symptoms related to intracranial hypertension. It is more difficult to establish that the risk for posttraumatic hemorrhage is reduced, as multiple case reports demonstrate that hemorrhage can still occur after treatment. In addition, although undoubtedly hemorrhage can have severe consequences, most patients reported to have had hemorrhage recover fully, some without surgical treatment.^{102,105,106,128,135,136} It is challenging to be clear about the likelihood that epilepsy will improve after arachnoid cyst treatment in the absence of

the concordant multimodality localization required in other pediatric candidates for epilepsy surgery. The relative consistency with which improvement is reported is encouraging, but in general, the methods of ascertainment and the length of follow-up are not adequate for us to be confident in the results. Treatment to improve preexisting static learning and behavioral difficulties is controversial, with the exception of treatment of the associated hydrocephalus. Several surgical series report improvement,^{132,143,145,146} but others do not.^{133,134} For young patients with very large cysts, it would be valuable to determine if there is a relationship between the degree of decompression and long-term cognitive outcome.

Pearls

- DWM catheters are prone to transcutaneous CSF leaks after initial placement. If a choice is made to place a cyst catheter, care should be taking to minimize the chances of leak by placing shunt hardware away from incisions and by paying attention to shunt valve pressure. Endoscopic options to avoid cyst catheters deserve consideration.
- Headaches and arachnoid cysts are both common and frequently coexist in patients but are not causally related.
- Children with suprasellar arachnoid cysts should undergo endocrinologic evaluation.
- Children less than 4 years of age at the time of diagnosis of an arachnoid cyst are at the highest risk for cyst expansion and should be followed with serial imaging in early childhood. Children older than 4 years at diagnosis are much less likely to exhibit cyst expansion and may reasonably be followed symptomatically.
- The incidence of intracranial hemorrhage in the setting of an arachnoid cyst less than 5 cm in diameter appears to be very low, and most patients who have an intracranial hemorrhage from an arachnoid cyst will recover fully. However, rare patients may present with hemorrhage requiring acute surgical care. Nevertheless, in many cases, an informed patient and family may reasonably accept the low risk for hemorrhage and continue with regular activities, including contact sports.
- Patients with arachnoid cyst shunts may present with significant intracranial hypertension at the time of shunt failure, even with a modest or minimally apparent change in cyst size.

14 Extracerebral Fluid Collections in Infants

Sandi Lam and David M. Frim

14.1 Introduction and Nomenclature

Many terms, such as benign subdural fluid collections of infancy, benign subdural hygroma, subdural effusion, benign external hydrocephalus (BEH), abnormally enlarged subarachnoid space, and subarachnomegaly, are in use. Many more terms, such as benign subdural collections of infancy, benign extra-axial fluid of infancy, and benign enlargement of the subarachnoid space, attempt to designate the condition as benign based upon radiologic studies alone. The terms benign external hydrocephalus, idiopathic external hydrocephalus, extraventricular obstructive hydrocephalus, and pseudohydrocephalus megaloccephaly include the word hydrocephalus despite minimal or no ventricular enlargement and minimal or no rise in intracranial pressure (ICP). The evolution of progressively better imaging modalities for the extracerebral spaces likely spurred on the process to refine and rename the visualized anatomical spaces and fluid collections over time, resulting in the multitude of terms used for the same or similar conditions. The nomenclature also likely reflects different theories of etiology and outcomes.¹ The terms are summarized in the box “Current and Historical Terms Used to Describe Enlargement of the Subarachnoid Spaces (p. 162).”

- Benign enlargement of subarachnoid spaces

Extracerebral fluid collections in infants reside in the spaces between the pia of the brain and the arachnoid (the subarachnoid space) and in the potential space between the arachnoid and the dura (the subdural space). Imaging of these collections in the infant is usually obtained for the evaluation of a large or enlarging head, as well as many other presentations. Idiopathic enlargement of the subarachnoid space is

commonly considered benign with no clinical or radiographic features suggestive of high ICP. The term *benign external hydrocephalus* (BEH) is the one most commonly used in the published literature. It is used in this chapter to refer to the constellation of findings presented above, although many other names have been applied to this entity. It is important to note that the word *hydrocephalus* is somewhat of a misnomer because BEH is not generally considered a pathologic or surgical diagnosis and is usually self-limited.

14.2 Anatomy of the Extracerebral Space

The anatomy of the extracerebral space can be conceptualized in layers. The pial surface of the brain marks the inner limit of the extracerebral space. The next layer is the arachnoid. Between the pia and the arachnoid is the subarachnoid space, which interdigitates into the cerebral sulci and overlies the cerebral gyri. The subdural space is the potential space outside the arachnoid and underneath the dural lining of the calvarial space.

The subarachnoid space is incompletely divided by arachnoid trabeculae.² The arachnoid and the arachnoid trabeculae are draped over pial vascular anatomical structures to maintain a relatively intact space overlying the entire supratentorial and infratentorial pial surfaces. The arachnoid and arachnoid trabeculae then expand into the extra-axial spaces to create cisterns.

The surface cerebrovascular tree of both large and medium-size arteries and veins is contained within the subarachnoid space. The arterial half of the subarachnoid vasculature enters the subarachnoid space essentially upon entering the cranial vault and subdural space. The arterial vasculature comes from both the carotid circulation and the vertebral circulation. The arterial tree is spread over the pial surface and penetrates the brain parenchyma at intervals to supply blood to the intraparenchymal capillary circulation of the brain.

Cerebral venous flow then goes in the other direction from the intraparenchymal capillary bed out of the brain parenchyma into the folds of the sulci and then into the subarachnoid space. Here, the veins coalesce and insert into large intradural venous sinuses. The venous subarachnoid vascular tree pierces through the arachnoid surface in many places into the true subdural space to feed directly into dural veins and venous lakes. These can be found as the veins enlarge and move closer to the large venous sinus structures, such as the superior sagittal sinus and the petrosal sinuses along the temporal bone.³ The Virchow-Robin spaces of cerebrospinal fluid (CSF), which are around the small blood vessels in the intraparenchymal space, may in fact be an extension of the subarachnoid CSF spaces along the brain-penetrating portions of the arteries.⁴ The relationship of these spaces to the enlargement of the subarachnoid space is not well understood.

The subdural space is a potential space in which the only recognized structure between the arachnoid and the dura is a segment of dural bridging veins. There may be a small amount

of CSF from an incompetent arachnoid membrane or from tracking along the traversing veins. The total length of the extra-arachnoid segment tends to increase as these veins approach the large venous sinuses. Any significant collection of fluid or other material, such as blood, in the subdural space is pathologic. There is no universally accepted or generally known function for the subdural space or the material within it.

14.3 Imaging of the Subdural Extra-arachnoid Space

14.3.1 Radiographic Anatomy and Imaging Characteristics of Benign Extracerebral Fluid Collections

Magnetic resonance (MR) imaging is the gold standard imaging modality for identifying the subarachnoid space versus the subdural extra-arachnoid space.⁵⁻⁸ Particularly on T2-weighted sections, traversing cortical veins can be visualized within subarachnoid fluid collections at the cerebral convexities; this is referred to as the “cortical vein” sign^{5,9} (► Fig. 14.1).

The arachnoid membrane overlying the subarachnoid space cannot be seen on the MR image unless pathologic fluid or other material exists on top of it in the subdural space, as in chronic subdural hematoma (► Fig. 14.2). Fluid in the subarachnoid space can clearly be differentiated from fluid or other material in the subdural space by the presence of a visible arachnoid membrane. Fluid in these spaces can be differentiated from CSF based on MR imaging signal intensity.⁸ The ability of MR imaging to discern various densities of protein within the fluid allows a much more detailed determination of the exact anatomical location of CSF versus other types of fluid.⁵

The subarachnoid space takes the shape of the gyri of the underlying brain, whereas the inferior boundary of the subdural space is smooth. Because of arachnoid trabeculae at the cortical sulci, the subdural space cannot interdigitate into the sulci. In cases of chronic subdural hematoma, the cortical vein sign is not present. Computed tomography (CT) as a

modality for identifying extracerebral fluids is less sensitive than MR imaging because the vessels of the subarachnoid space are more difficult to visualize. CT can identify 90% of subdural fluid collections, whereas MR imaging is estimated to be 100% sensitive.¹⁰

In infants with open fontanels, the distance between the dura and the pial surface of the brain can easily be assessed by transfontanel ultrasonography.^{11,12} However, the examination is limited to the cone of ultrasonographic vision through the fontanel, as well as being limited by artifact from the skull bone.

Clinically, it is difficult to draw conclusions about the exact anatomical location of the fluid in the extracerebral space or the nature of that fluid without MR imaging or, when needed, analysis of a fluid sample drawn percutaneously. Intravenous contrast neuroimaging studies show the rapid influx of contrast medium from CSF into the subarachnoid fluid spaces but not into fluid in the subdural extra-arachnoid compartment.¹³

The frontal subarachnoid spaces are enlarged beyond the upper defined limits for age in the setting of benign extracerebral fluid collections, and the cortical vein sign is visible on T2-weighted MR imaging. The ventricles are generally normal or moderately enlarged in size. The interhemispheric fissure is often but not always wider than normal; as well, the third ventricle and basal cisterns are larger than normal.¹⁴⁻¹⁷

Benign extracerebral fluid collections can be distinguished from global cerebral atrophy because the latter is associated with widening of the cerebral sulci globally and, not concentrated in the nondependent subarachnoid space, such as the frontal areas visualized in a supine patient.¹⁵ As well, cerebral atrophy is not associated with increasing head circumference.

14.3.2 Normal Measurements of the Subarachnoid Space

There is no consensus on the definition of normal subarachnoid space size. There is no significant difference between reported subarachnoid space sizes in male and female children.¹⁸⁻²⁰ In neonates, the maximal upper measurement limit of the

subarachnoid space width is reported to range from 3.3 to 5 mm.^{18,20,21} In infants younger than 1 year old, the maximal upper limit of normal subarachnoid space width is reported to range from 4 to 10 mm.^{16,19,22–24} Upper values for the interhemispheric fissure width range from 6 to 8.5 mm, and for the distance between the lateral wall of the superior sagittal sinus and the cortical surface (sinocortical width), they range from 2 to 10 mm.^{1,22–26} Variations in the size of the subarachnoid spaces are observed during growth, with the upper limit of normal width reported to increase from birth to 7 months,¹⁹ to decrease from 1 to 2 years of age,²³ and to become essentially absent after 2 years of age.^{27–29}

14.4 Identification and Pathophysiology of Fluid within the Extracerebral Spaces of the Infant

14.4.1 Identification

Fluid within the subarachnoid space in the nonpathologic state is CSF. Other fluids that can be present within the subarachnoid space endogenously are blood products or pus from a purulent infection of the surface of the brain. Fluid within the subdural space that is purely extra-arachnoid can be CSF transudate, blood (such as from rupture of a subdural bridging vein), blood transudate, or purulent material from an extra-arachnoid subdural abscess. Blood in its acute state in the subarachnoid or subdural space can be solid or gelatinous clot. The treatment of acute subdural hematoma or acute subarachnoid hemorrhage is outside the scope of this chapter and is discussed elsewhere in this volume. Once subdural or subarachnoid blood lyses to become a proteinaceous liquid, it falls within the rubric of an extracerebral fluid collection. Nongelatinous hemorrhage within the subarachnoid space tends to resolve over days to weeks because the subarachnoid space is a low-flow CSF space,^{30,31} whereas hemorrhage in the subdural space can take much longer to resolve because of the absence of CSF flow. Rupture of the arachnoid membrane, from trauma or surgical manipulation, fuses the subdural and the subarachnoid space for a time before the brain itself has the opportunity to scar to the underside of the dura, which may frequently happen. In that situation, in which the anatomical boundaries are blurred, the fluid mixture is more difficult to diagnose but can be some combination of CSF, blood, and pus.

Blood in the subdural space undergoes a transition from solid clot to eventual resolution by lysis and resorption. During this progression, the blood can become bounded with subdural membranes, which are a fibrous encapsulation of the original clot that is vascularized.^{32,33} There is extensive literature on subdural membranes and their development and resolution. The membranes tend to enhance with gadolinium.^{34,35} The membranes also elaborate tissue plasminogen activator (tPA) and bradykinin, which can cause further or recurrent hemorrhage, spilling more and more blood into the subdural space.^{36,37} This creates a laminar hierarchy of hemorrhages in various states of resorption, with intervening membranes that become progressively thinner with time. The anatomical localization of these membranes also becomes farther and farther away from

the dura, which appears to be the origin of their blood supply.³⁸ The stages of resolution of subdural hematomas have been well described in the literature.^{39,40}

Infection within the subdural space can be gelatinous, fluid, or a combination of both. The most accurate term for this infection is *subdural empyema*. Subdural empyema can involve both the subdural space and the subarachnoid space, which is observed on imaging and during intraoperative inspection.^{41,42} It is frequently associated with sinusitis and is thought to migrate along the valveless veins in the subdural space.^{42,43} The term *subdural effusion* has been used to describe a hypodense fluid accumulation associated with meningitis, such as in the case of *Haemophilus influenzae* infection.⁴⁴ The term *subdural effusion* has also been applied to hypodense subdural fluid collections in the setting of trauma, adding ambiguity to the terminology used for these lesions. No matter what scheme of nomenclature is used, the anatomical components of the extracerebral space are as presented, and the fluid can comprise only CSF, blood (either acute or during a phase of resolution), or an exudate from a blood clot or an abscess. This concept allows a simplified interpretation of the nomenclature and of the pathologic entities involved.

14.4.2 Pathophysiology

A number of theories about the pathophysiology of BEH exist, although the etiology is not completely understood. The most common theory is that the arachnoid villi are not mature, with a resultant inability to absorb CSF effectively, which leads to CSF accumulation in the subarachnoid space.⁴⁵ With a relative impediment to the low-pressure resorption of CSF from the subarachnoid space through the arachnoid into the superior sagittal sinus, the subarachnoid space enlarges. The ventricles of the infant with an enlarged subarachnoid space may also appear to be mildly dilated and at the upper limit of normal.^{46,47} The sylvian fissures and sulci are also slightly enlarged. As the cranial sutures are not fused in this age group and the skull is compliant, a marked increase in ICP is generally avoided, whereas macrocephaly is common. Heredity is suggested to play a role, as more than 40% of children with BEH are reported to have a familial form, with one or more close relatives being macrocephalic and having a head circumference at or near the 98th percentile.^{5,28,46,48–52} BEH also reported to occur in twins and triplets. The phenotype may be related to delayed maturation of the arachnoid villi.¹⁵ Follow-up evaluation of many of these patients shows that the parenchymal brain volume appears to conform to a normal configuration by 3 or 4 years of age,^{28,29} supporting spontaneous resolution of an underlying problem, such as immature arachnoid villi, which mature at age 18 months.^{1,53}

Supporting the idea of mildly impaired CSF resorption is the observation that conditions with increased central venous pressure, such as right-sided heart failure and pulmonary disease, enlarge the subarachnoid spaces, presumably through impeded resorption.^{15,54,55} (► Fig. 14.3) Additional correlation between increased CSF spaces and rigid venous outflow impedance comes from observations in craniosynostoses, plagiocephaly, and hydrocephalic achondroplastic dwarfs.^{56–59}

Enlarged subarachnoid spaces may be on the spectrum preceding internal hydrocephalus in children with communicating

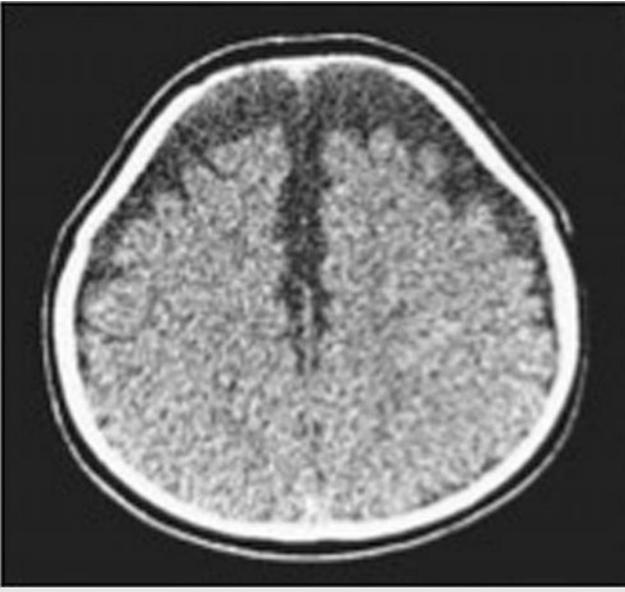

Fig. 14.3 Axial noninfused computed tomographic scan of the head of a 3-month-old girl with right-sided heart failure and a bulging fontanel demonstrating enlargement of the subarachnoid space.

hydrocephalus if the arachnoid granulations remain dysfunctional, with CSF accumulating in the subarachnoid space and then subsequently in the ventricular system over time.^{29,60} However, there is a distinction between delayed maturation of the arachnoid villi with regression of the problem after the age of 18 months and agenesis of the arachnoid villi with necessity for surgical CSF diversion.^{53,61}

Another theory for the pathophysiology of BEH is cranioccephalic disproportion, with the skull transiently growing at a faster rate than the brain. The brain growth is believed to be slow in these children, and after a lag period, the brain begins again to fill the cranium.^{15,50,62,63}

The developmental pathophysiology of benign enlargement of the subarachnoid spaces is not completely understood. In our experience, BEH has not progressed to frank hydrocephalus with an enlarged fluid space under inappropriately high pressure unless it is complicated by infection or hemorrhage; however, such rare occurrences have been reported in the literature.^{46,64–66} In the setting of presumed mild malabsorption of fluid, a small amount of blood mixed into the subarachnoid CSF can cause the pressure to increase, so that extracranial shunting is eventually required, as in absorptive hydrocephalus with ventricular enlargement having other causes.²⁹ Purely subdural bleeding might not lead to such a problem because it would not mix with the CSF in the subarachnoid space.

Blood found in the subdural space is generally thought to come from the disruption of bridging veins, which penetrate the arachnoid after draining the cortical surface and then insert into the underside of the dura or directly into a dural venous sinus structure.⁶⁷ Various issues around the acute management of subdural hematoma are discussed in other chapters. As an extracerebral fluid collection, subdural blood can be of small volume or can mix with the CSF of a ruptured arachnoid membrane. As a purely subdural collection, blood will coagulate and then organize into a mature clot. At that

point, it may become encapsulated by membranes and then be slowly reabsorbed. A chronic subdural hematoma is not stable because ongoing bleeding from the membranes can increase the size of the fluid collection and turn a relatively small initial hemorrhage into a lesion causing mass effect.⁶⁸ It can also increase the tension on already stretched veins, leading to repeated rupture from minor trauma or inertial changes. As the blood is resorbed, the fluid collection will become less dense, a change visible on CT and MR imaging; however, it can easily be differentiated from BEH by the lack of visible subarachnoid vessels (i.e., no cortical vein sign). The vessels in the subarachnoid space would not enter into an isodense chronic subdural hematoma in its late phase.

A connection between BEH in childhood and the development of normal-pressure hydrocephalus (NPH) in the elderly has been suggested, with a two-hit hypothesis of childhood BEH followed by deep white matter ischemia leading to symptoms in later years.⁶⁹ Patients with NPH have significantly larger intracranial volumes than control subjects on imaging,⁷⁰ and 20% of patients with NPH have head circumference measurements over the 90th percentile.⁷¹ The possible link between BEH and later NPH has yet to be fully explored and may offer future insights into natural history and management.

14.4.3 Associated Conditions

BEH has been associated with developmental delay^{50,72–76} and an increased theoretical and observed risk for subdural hematoma.^{7,77–79} Other reported associations include prematurity and intraventricular hemorrhage,^{80–83} meningitis,^{81,84} metabolic disorders,^{85,86} and certain medications, such as chemotherapeutic agents.⁸⁷ BEH has also been associated with raised venous pressure, such as in systemic disease, thoracic conditions, and right-sided heart failure.^{15,54,55} Rigid venous outflow obstruction and thus raised venous pressure in craniosynostoses, plagiocephaly, and achondroplasia have been reported to cause external hydrocephalus.^{56–59} Syndromes associated with enlarged subarachnoid spaces include achondroplasia, Sotos syndrome, Beckwith syndrome, Weaver syndrome, and Goldenhar syndrome.²⁸

Fetal MR imaging studies show that 19% of those with mild ventriculomegaly and large subarachnoid spaces prenatally later carried a diagnosis of BEH as infants.⁴⁷ The prominent subarachnoid spaces seen prenatally are distributed more posteriorly; this pattern reflects the formation of the subarachnoid space as a cavitation of the primitive meninges from the ventral to the dorsal portion of the neural tube.⁸⁸

14.4.4 Implications for the Evaluation and Diagnosis of Nonaccidental Head Trauma

Although isolated subdural hematoma without a known intervening trauma can be a sign of nonaccidental trauma, it appears that our knowledge of the pathophysiologic mechanisms for subdural hematoma in the setting of preexisting BEH is incomplete. There are ongoing investigations on the infant shaking impact syndrome.^{89–91} BEH may predispose toward subdural hematoma from an impact that would otherwise not cause a

subdural hematoma in a child with normal-size subarachnoid spaces. The proposed etiology is stretching of bridging veins in the enlarged subarachnoid spaces. The risk for developing subdural hematoma is reported to be higher in children with BEH after minimal or no trauma to the head.^{6,7,78,79} Because of these observations, subdural hematoma is not considered pathognomonic for nonaccidental trauma in situations in which BEH is present. A careful search for other evidence in the context of a full evaluation for nonaccidental trauma must be made in the patient with BEH and subdural hematoma before child abuse is diagnosed. In the absence of other evidence, the diagnosis of nonaccidental trauma cannot be based solely on the presence of a chronic subdural fluid collection in a child with BEH and no history of significant head impact.

14.5 Epidemiology

The incidence and prevalence of BEH are not known. A review of the records of a tertiary pediatric neurology practice notes that 0.6% of patients were diagnosed with BEH.⁹² Approximately two-thirds of children with BEH are male.^{48,93} BEH is reported to be the most common cause of macrocephaly in infants in developed countries.^{28,94}

Most studies report a familial pattern, and from 40 to 80% of children with BEH have at least one close relative with macrocephaly and a head circumference measuring above the 98th percentile.^{5,28,46,48-52} BEH has been reported in twins and triplets, suggesting a genetic component.^{31,95} The inheritance pattern is postulated to be autosomal-dominant or multifactorial, with a gene exerting an effect during a limited period of susceptibility in development, such as a delay in the maturation of arachnoid villi.^{15,60,96}

14.6 Clinical Presentation of Extracerebral Fluid Collections in the Infant

Extracerebral fluid collections can present like any intracranial mass lesion. In BEH, the presentation is recognized by a large head circumference that may be crossing percentile markings in the first several months of life.^{28,62,76} The fontanel will generally be soft and will be concave upon sitting. The sutures will not be split. Occasionally, the child may also present with positional plagiocephaly, which has a correlation with BEH⁵⁸ (► Fig. 14.4).

Most commonly, the growth trend in the head circumference of a child with BEH stabilizes in relation to the percentile growth curves by 18 months of age. Children with BEH who have had radiographic follow-up demonstrated spontaneous resolution of frontal subarachnoid enlargement within 2 to 3 years, with no recurrence of the enlarged subarachnoid fluid space once it resolved.^{14,15,29,49,97}

The child with BEH may have gross motor delay consistent with a large head, which may decrease the child's ability to move and roll early in life. This delay should disappear as the proportion between the head and the body changes with growth. In addition to delay in gross motor skills, delay in

speech and language and other neuropsychological delay have been reported. Most of these delays are reported to decrease or disappear in 1 to 4 years. In a review of the literature, up to 17% of children with 2- to 5-year follow-up had abnormal psychomotor development.^{1,72,97}

Bleeding into the enlarged subarachnoid space, either externally from disruption of the arachnoid membrane after trauma with concurrent subdural hematoma or internally from subarachnoid hemorrhage, may cause progressive hydrocephalus. The clinical presentation at this point would be that of raised ICP in an infant, including convex bulging of the fontanel, splitting of the sutures, and rapid head growth. Other signs of increased ICP, such as irritability, may also be present.

Blood in the subdural space can cause cortical irritation leading to seizure.⁹⁸ Subdural hematomas can also enlarge to cause mass effect and focal neurologic deficits, such as hemiparesis. In its more indolent form, an enlarging chronic subdural hematoma can cause convex bulging of the fontanel and splitting of the sutures, as does any enlarging fluid collection in the brain of an infant. The presence of a subdural hematoma in a child with increased subarachnoid space may not follow recognized head trauma.^{7,77,79} The predisposition of children with BEH to subdural hematoma has been recognized. A potential etiologic factor may be the increased length of the subarachnoid and subdural veins. This allows prediction based on mathematical modeling of venous disruption, with relatively less impact to the cranium than would happen in children with thinner subarachnoid spaces and shorter veins.⁷⁷ Implications for the investigation of nonaccidental head trauma are aforementioned.

14.7 Treatment of Extracerebral Fluid Collections in the Infant

It is important to note that no randomized controlled studies exist comparing treatment and nontreatment for BEH. A large majority of children are managed conservatively. No comparative studies or large-scale cohort studies have been done to examine the effect of observation or of intervention on BEH. Neuropsychological testing, developmental assessments, and long-term follow-up in larger studies are needed to further understand this entity.

BEH usually has a benign course and is self-limited. Only when it progresses to a true malabsorptive hydrocephalus does it require any sort of fluid diversion. In the absence of some additional factor that decreases the amount of CSF absorbed from an enlarged subarachnoid space, typically no treatment is indicated for enlarged subarachnoid spaces. In the situation of traumatic hemorrhage mixing into the CSF of a patient with enlarged subarachnoid spaces, there may be a transient period of elevated ICP that can be treated by one or more percutaneous taps into the extracerebral space.⁶⁸ If a chronic subdural collection develops, it may also require several days of continuous external drainage to obliterate the extracerebral space and make the recurrence of elevated ICP from subdural fluid unlikely.⁹⁹ It is rare, but the persistence of extra-axial fluid collections can require temporary, self-contained shunt placement.^{100,101}

Bleeding into the subdural space from the rupture of a subdural bridging vein can be an acute problem presenting with life-threatening intracranial hypertension. The treatment of this problem is discussed elsewhere in this volume.

A loculate fluid collection in the extra-axial space on imaging after a distant trauma or unrecognized trauma is likely to be a chronic subdural hematoma. The diagnosis can be made based on percutaneous subdural tapping, which will yield bloody fluid with xanthochromia. If the chronic subdural hematoma is in its late phase, such a tap may reveal only a clear yellow fluid. Concurrent lumbar puncture may show clear CSF, or if the arachnoid membrane was ruptured by the initial trauma, the CSF throughout the neural axis may be of the same color. Because the subdural space is anatomically separate from the subarachnoid space, we emphasize that blood wholly in the subdural space should not cause hydrocephalus; although in its late phase, the chronic subdural hematoma can enlarge and cause mass effect as a loculate fluid collection. This will need treatment by continuous drainage for several days,⁹⁹ which will obliterate the space (especially when it is membrane-bound). The historical approach of “stripping the subdural membranes” in this situation may not be necessary, as entry into all loculate spaces with bur hole or percutaneous drainage may suffice to obliterate loculation. Continuous drainage through a subdural drain to an external collection bag may allow obliteration of the space and approximation of the layers of the subdural collection, where they will scar together. Needle aspiration has been used in the past but has been reported to be rarely effective as definitive management; therefore, it is reserved for use as a diagnostic measure.¹⁰²⁻¹⁰⁴ We recommend the treatment of symptomatic bilateral chronic subdural

hematomas with continuous external drainage for up to 7 days with standard ventricular catheters and careful attention to electrolyte balance and infection avoidance. If fluid drainage ceases before 7 days and CT shows obliteration of the subdural space, the drains may be removed earlier. Occasionally, the treatment of a chronic subdural hematoma in its late phase may necessitate a subdural-to-peritoneal shunting device. If the subdural collections return following drain removal, placement of a unilateral subdural-to-peritoneal shunt with a low-pressure valve is recommended.¹⁰⁵ Follow-up CT is recommended 1 month after shunt placement to ensure bilateral drainage from a unilateral shunt. The need for subdural fluid diversion is often not permanent, which may reflect resolution of the inflammation in the absorptive surface or obliteration of the subdural space. Although not required, the shunting device may eventually be removed to avoid future shunt-related complications.

A common scenario encountered by the practicing neurosurgeon is an infant with macrocephaly and mild developmental delay whose CT scan shows BEH and mild ventriculomegaly. The assessment of such a patient should begin with the history, a physical examination, and a thorough radiologic evaluation. The history and physical examination can distinguish between congenital, traumatic, and infectious etiologies; the family history can assess syndromic causes and familial macrocephaly. In particular, careful measurement and charting of the parental head circumference may reveal familial macrocephaly, which is commonly associated with BEH, with emphasis on the benign course. In many cases, this may allow the cessation of further work-up in favor of a period of observation.

High-resolution coronal T2-weighted MR imaging can distinguish between BEH, chronic subdural hematoma, and an infectious subdural fluid collection. If idiopathic BEH is diagnosed, then a careful evaluation of the degree of developmental delay should be made. If the developmental delay is limited to deficiencies in head control based on an altered center of gravity in an infant with macrocephaly, then conservative observation is recommended. However, if the developmental delay is more profound, then a lumbar puncture may be warranted, although the results of a lumbar puncture may be difficult to interpret with respect to the present literature on the topic.

A review of the literature on external hydrocephalus shows a lack of consensus concerning the role of raised ICP, likely because of the inclusion of heterogeneous groups in the studies of this condition. Few studies report direct measures of intracranial or intrathecal pressure.^{51,75,106} In these reports, an effort was made to exclude hydrocephalus and other syndromic, traumatic, or infectious macrocephalic etiologies. The ICP values reported range from normal to slightly increased, from 6 to 16 mm Hg.¹ Other articles examining macrocephaly and BEH used indirect evidence of raised ICP, such as bulging fontanel, engorged scalp veins, and clinical improvement after medical or surgical treatment. Twenty-five patients showed some signs and symptoms of raised ICP,^{45,73,107} and 39 showed a lack of evidence of intracranial hypertension.^{45,50,82} These data are confounded by the combination of chronic hematomas, effusions, and syndromic macrocephaly. As well, the possibility of raised venous pressure creating BEH must be identified and, if possible, treated.¹⁰⁸

Increased ICP, defined as an opening pressure greater than 15 cm H₂O, appears in the minority of cases of BEH in the literature. This should require treatment, typically with the placement of a CSF shunt. Some studies discuss medical management with acetazolamide (Diamox; Teva, North Wales, PA), but only short-term improvement is reported.^{14,45,109} Good outcomes are reported from shunting, although these cannot be interpreted meaningfully as the cases illustrated are highly selected and represent a small and heterogeneous group. As external hydrocephalus is thought to be due to disturbances of CSF absorption (see section on pathophysiology) and thus anatomically can be classified as a communicating hydrocephalus, insertion of a ventriculoperitoneal shunt is the most appropriate intervention when surgical treatment is indicated.^{1,110} Lumbar-peritoneal shunting is not recommended and has been associated with the potential for ventriculomegaly in this scenario.¹¹¹ Subdural-to-peritoneal shunting is also not recommended for external hydrocephalus as it does not directly address the CSF compartment; the CSF in BEH lies in the subarachnoid space, not the subdural space. We recommend ventriculoperitoneal shunt placement in the instances when infants with enlarged extracerebral subarachnoid spaces exhibit signs and symptoms of increased ICP requiring surgical treatment.

14.8 Conclusion

Significant nomenclature exists to describe extracerebral fluid collections in young children. When the naming of this finding is based on the anatomy of the subarachnoid and subdural spaces, the major entities that comprise extracerebral fluid collections are benign external hydrocephalus, chronic subdural hematoma in early and late phase, and subdural empyema. Once the pathophysiology is clearly delineated, its evaluation, diagnosis, and treatment generally follow logically, although the etiology of benign external hydrocephalus is not completely understood.

Pearls

- Macrocephaly in an infant with enlarged subarachnoid spaces is usually benign. High-resolution T2-weighted MR imaging is most useful in distinguishing macrocephaly from chronic subdural hematoma in the late phase.
- When BEH is encountered, look for familial macrocephaly, right-sided heart disease or pulmonary disease, or prematurity as an associated etiology. Developmental delay needs to be evaluated.
- The parents of children with BEH should be advised about the theoretically increased risk for hemorrhage into the enlarged subarachnoid spaces in minor head trauma and for the association between BEH and positional head molding.
- Chronic subdural hematoma in the late phase can cause elevated intracranial pressure and requires drainage percutaneously, by external drainage, or by subdural-to-peritoneal shunt placement.
- Isolated, unexplained subdural hematoma in a relatively healthy child with underlying BEH cannot be considered pathognomonic for nonaccidental trauma in the absence of other medical or social evidence suggestive of abuse.

15 Congenital Intracranial Malformations

Jonathan D. Bui and Tien T. Nguyen

Congenital malformations of the brain comprise a large and diverse set of anomalies that result in a wide range of functional outcomes for affected children—ranging from relatively benign neurologic deficits to severe deficits that are incompatible with life. The nervous system develops in an orchestrated manner, regulated by numerous proteins that signal the proliferation, migration, and differentiation of primordial cells into the functioning neurons and supporting structures that make up the human nervous system. Cerebral malformations, thus, can result from dysfunction along this highly regulated embryogenic pathway through genetic, metabolic, infectious, and in utero environmental abnormalities. Advances in neuroimaging make possible the identification of more subtle malformations. In addition, the increasing availability of high-resolution microarray-based comparative genomic hybridization (aCGH) genetic testing has allowed a more precise diagnosis than ever before. In fact, the explosion in our knowledge of the genetic and molecular controls involved in brain development is shedding new light on the etiologies of congenital malformations, raising the possibility of improving our management of these often devastating conditions.

Based on the current understanding of abnormal embryology, the major malformations are grouped as supratentorial or infratentorial (see boxes “Classification of Supratentorial Malformations (p. 171)” and “Classification of Infratentorial Malformations (p. 171)”). As we continue to gain more knowledge of the developing brain in the future, the classification will likely be altered. A detailed description of the development of the central nervous system (CNS) is covered in another chapter. We discuss embryology only briefly here as it pertains to the various congenital malformations. The chapter concludes with some general comments and recommendations regarding their diagnosis and surgical management.

Classification of Supratentorial Malformations

- Disorders of neurulation
 - Anencephaly, craniorachischisis
 - Cephalocele (encephalocele)
 - Congenital dermal sinus
- Disorders of ventral induction
 - Holoprosencephaly
 - Septo-optic dysplasia
 - Dysgenesis of the corpus callosum
- Abnormal neuronal proliferation or apoptosis
 - Reduced proliferation or excess apoptosis
 - Microcephaly
 - Microlissencephaly
 - Megalencephaly
 - Cortical dysgenesis with abnormal cell proliferation
 - Hemimegalencephaly
 - Type 2 focal cortical dysplasia
 - Congenital neoplasia
- Abnormal neuronal migration
 - Neuroependymal abnormality

- Periventricular (subependymal) heterotopia
- Abnormal transmantle migration
 - Lissencephaly/subcortical band heterotopia
- Abnormal late transmantle migration
 - Subcortical heterotopia
- Abnormal terminal migration
 - Cobblestone complex
- Abnormal postmigrational development
 - Polymicrogyria
 - Polymicrogyria with schizencephaly
 - Polymicrogyria without schizencephaly
 - Focal cortical dysplasia
 - Type 1 focal cortical dysplasia
 - Type 2 focal cortical dysplasia
 - Microcephaly

15.1 Types of Congenital Intracranial Malformations

15.1.1 Anencephaly

Anencephaly is the most severe of the neural tube defects (NTDs), resulting in the absence of major portions of the brain and skull. Like craniorachischisis and spina bifida, anencephaly occurs when the rostral neural tube fails to close. Apposition and fusion of the neural apices at the dorsal midline occur between the third and fourth weeks of gestation. The fusion begins at the primitive hindbrain–cervical junction, referred to as

closure 1, and spreads in both a rostral and a caudal direction. Additional points of fusion occur at the most cephalic end of the embryo, known as closure 3, and at a variable location between closures 1 and 3, known as closure 2.^{1,2} A defect in fusion of the anterior neuropore, between closures 1 and 3, at approximately gestational day 24, results in anencephaly (► Table 15.1).³ Initially, a rudimentary cerebrum can exist, resulting in what is known as anencephaly (► Fig. 15.1), but the exposed brain is subject to injury from amniotic fluid and in utero mechanical trauma. As a result, stillbirths are common with anencephaly, but a third of affected fetuses are born alive. Unfortunately, there is no effective treatment, and these newborns survive only hours. They are thought to be not capable of consciousness or of experiencing pain owing to the lack of cerebral development.⁴

The diagnosis of anencephaly can be made prenatally by screening alpha fetoprotein and ultrasound. Currently, anencephaly occurs an estimated 1 in 1,000 births in the United States,^{5,6} although there are significant geographic, racial, and socioeconomic variations. However, because of the option of pregnancy termination after prenatal diagnosis, the exact incidence is difficult to determine. The introduction of maternal folic acid supplementation has resulted in a significant decline of NTDs worldwide, including anencephaly.

15.1.2 Cephalocele

A cephalocele (or encephalocele) is a rare form of NTD in which the cranial contents protrude through a congenital defect in the cranium. It can be further classified based on the contents. A cranial meningocele contains only meninges, whereas an encephalomeningocele or encephalocele contains both meninges and brain tissue (► Fig. 15.2). An encephalocystocele or hydrencephalomeningocele also includes a dilated ventricle. These malformations are a result of failure of the neuroectoderm to separate from the surface ectoderm during neural tube closure, which leads to a mesodermal defect and prevents proper ossification of the skull. If the skull defect is sizeable, meninges and brain can herniate through the opening, resulting in a meningocele or cephalocele. The sac, which is often at the midline, is covered by normal or dysplastic skin, and thus, maternal serum alpha fetoprotein is typically normal. Cephaloceles in the occiput are most often seen in North America, and those in the frontal region, particularly the nasofrontal, nasoethmoidal, or naso-orbital region, are common in Southeast Asia, certain parts of India, and Africa.^{7,8} The prognosis depends on the location of the lesion, the presence and size of brain herniation, and other congenital anomalies. Cephaloceles can be associated with cerebellar dysplasia, lissencephaly, hypoplastic brainstem,

and Dandy-Walker malformations, as well as cleft lip, cleft palate, hypertelorism, microphthalmia, anophthalmia, syndactyly, and heart defects. Surgical options must be discussed in this context.

15.1.3 Congenital Dermal Sinus

A dermal sinus is a tract lined by keratinized squamous epithelium originating from a skin dimple with variable intracranial or intraspinal extension. It results from a focal adhesion and incomplete dissolution of the continuity between the neural and cutaneous ectoderm during neurulation, around the fourth week of gestation.^{9,10} The persistent tract can occur anywhere between the columella of the nose and the coccyx. Nearly all reported cranial cases occur in the midline and most commonly involve the external occipital protuberance (85%) and less often the nasion (10%) and the posterior parietal area (5%). Inclusion cysts (dermoid cyst, epidermoid cyst, and teratoma) may exist at any point along the tract.^{11–13} Dermal sinuses can connect the skin surface to any depth within the CNS and thus can be a source of intracranial infections and should be excised.¹⁴

15.1.4 Holoprosencephaly

Holoprosencephaly (HPE) is the most common developmental disorder of the human forebrain and is the result of failure of the forebrain to divide into two distinct hemispheres. Although it occurs once in every 250 conceptuses, most of these do not survive to term, and HPE is seen in only 1 in 10,000 live births and stillbirths.^{15,16} Few such newborns

survive past 1 year.¹⁷ HPE appears to be more common in girls, nonwhite races, and multiple-gestation pregnancies. Newborns with HPE often have a low birth weight. Genetic and environmental causes of HPE are thought to disrupt the prechordal plate during early gastrulation and the neural plate during neurulation.^{15,18} Perturbation of the prechordal mesoderm disrupts neural induction and regional patterning, both of which are critical to normal forebrain and midface development. Nonsyndromic, nongenetic causes are not common, and implicated teratogens include maternal diabetes, ethanol, antiepileptic drugs, retinoic acid, cigarette smoking, congenital cytomegalovirus infection, and alkaloids of the plant *Veratrum californicum*.^{19–21}

More than a third of patients with HPE have chromosomal number abnormalities, particularly trisomy 13, followed by trisomy 18 and triploidy, as well as certain malformation syndromes, such as Smith-Lemli-Opitz syndrome.^{22,23} Transmission can be autosomal-dominant, autosomal-recessive, or X-linked. The primary pathway implicated in HPE and other midline defects is the Sonic Hedgehog (SHH) signaling pathway.²⁴ Inheritance of HPE exhibits an 80% penetrance, most commonly related to several genes, including *SHH* on 7q36, *ZIC2* on 13q32, *SIX3* on 2p21, and *TGIF* on 18p11.3.²⁴ Less common genes implicated include *GLI2* on 2q14 and *NODAL* on 10q22.11. Disrupted gradients of gene expression along the three anatomical axes are thought to be elementary in the pathogenesis of HPE. Variations in the timing and location of gene mutations help to account for the diverse phenotypic spectrum in those affected by HPE. The genetics of HPE is thought to be a complex, multiple-hit process because a genetic mutation cannot be identified in up to 83% of HPE cases, although the increasing use of aCGH is beginning to change the landscape.^{15,24}

The classification put forth by DeMyer and colleagues in the 1960s still serves as a useful starting point in understanding this heterogeneous disease.²⁵ The most severe form, alobar HPE, is characterized by an almost complete lack of midline cleavage between the hemispheres, resulting in the classic “monovertricle” of the forebrain (► Fig. 15.3). This single ventricle is often associated with a dorsal cyst, and there is no identifiable corpus callosum or interhemispheric fissure. Semilobar HPE forms when there is some separation of the posterior hemispheres and occipital horns but the anterior hemispheres and associated ventricles fail to separate. Most of the corpus callosum fails to develop, except for the splenium. The least severe form of classic HPE is the lobar type, in which the lack of midline cleavage is restricted to the rostral–ventral forebrain with near-normal separation of the remainder of the forebrain. The corpus callosum is normal with the exception of the genu. A more recently recognized and milder subtype of HPE, known as the middle interhemispheric variant, results from the failed separation of the posterior frontal and parietal lobes but spares the rostral–ventral frontal area.^{17,26}

Superimposed on the different forms of HPE described above is variability in the cleavage of the deep gray nuclei.²⁷ In every case of HPE, there is some degree of hypothalamic noncleavage. The next most likely deep gray structures not to cleave are the caudate nuclei, followed by the lentiform nuclei and finally the thalami, which remain fused in 67% of patients. The extent of fusion of these deep gray nuclei, particularly the

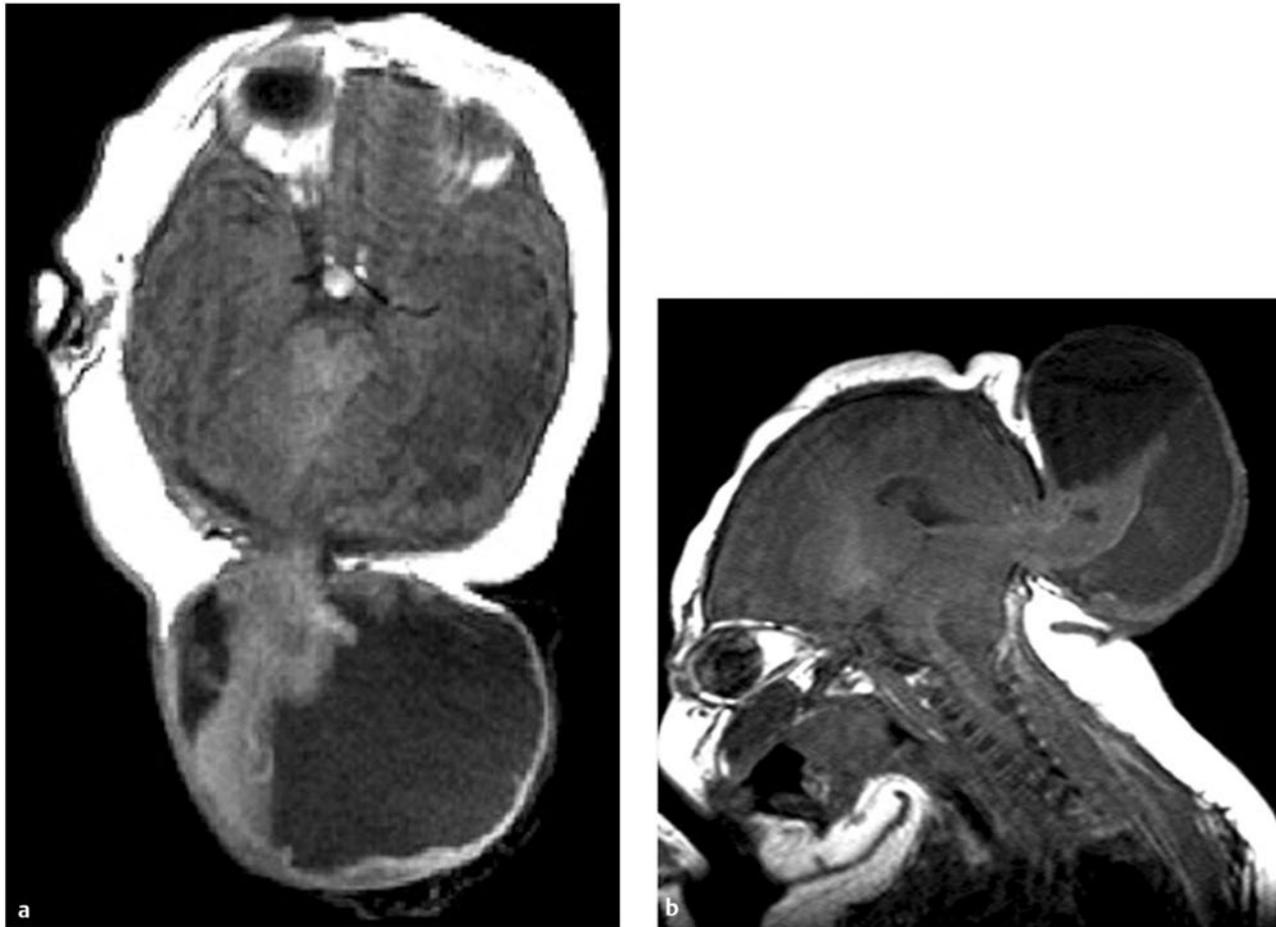

Fig. 15.2 Axial T1-weighted (a) and sagittal T1 weighted (b) magnetic resonance images of a newborn with occipital cephalocele show suboccipital cranial defect and herniated cerebellum.

basal ganglia and thalami, is proportional to the hemispheric noncleavage described by DeMyer and has prognostic value for neurologic outcome.²⁸ However, there are noted exceptions to this trend, which may in part account for the variation in the severity of neurologic dysfunction among patients with the same type of HPE under DeMyer's classification. The variability of morphologic nonseparation and phenotypic expression of HPE precludes a simple and accurate prognosis for each patient.

It has long been observed that the “face predicts the brain.” In other words, the various forms of midface hypoplasia often associated with HPE serve as markers of the underlying fore-brain abnormalities.²⁹ Severe midface abnormalities, such as cyclopia, ethmocephaly, and cebocephaly, often coincide with alobar HPE.^{18,30} Other associated midline abnormalities can be relatively subtle and include arhinencephalia, agenesis of the corpus callosum, pituitary abnormalities, median cleft lip, and the presence of a single maxillary central incisor.³¹ Clinically, patients can present with oral motor dysfunction, seizures, endocrinopathies (especially diabetes insipidus), microcephaly, hydrocephalus, dystonia, spasticity, choreoathetosis,

and developmental delay. The hydrocephalus and third ventricular dorsal cyst of alobar HPE are related to blockage of the outlet of the third ventricle in conjunction with aqueductal stenosis.²²

15.1.5 Hydranencephaly

Hydranencephaly results from destruction of a previously normally developing brain by in utero vascular occlusions and hemorrhages, infection, or maternal exposure to drugs, cigarette smoking, or radiation.³² The hemispheres corresponding to the middle cerebral artery or, more often, the entire anterior circulation is resorbed and replaced with cerebrospinal fluid (► Fig. 15.4). The thalamus, brainstem, and cerebellum are spared along with the meningeal sac and falx. There may be a small residual occipital, frontal, or temporal cortex present. Hydranencephaly, which appears on imaging as nearly complete absence of the cerebral hemispheres, can be difficult to differentiate from HPE with hydrocephalus. The presence of a falx and separate thalami, along with the absence of facial anomalies and the frontal cortical mantle, distinguishes hydranencephaly from HPE.

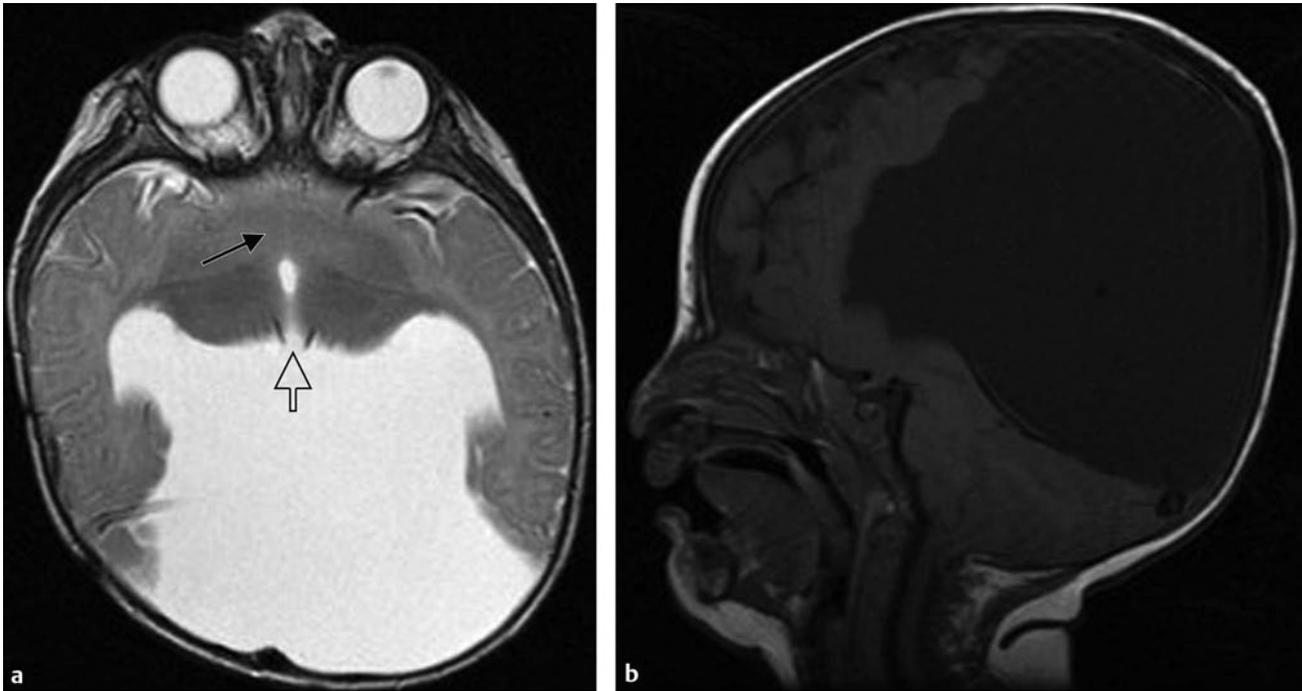

Fig. 15.3 Axial T2-weighted (a) and sagittal T1-weighted (b) magnetic resonance images of a child with alobar holoprosencephaly show fused basal ganglia (arrow) and a monoventricle that opens to a dorsal cyst. The thalami are partially fused (open arrow).

15.1.6 Septo-optic Dysplasia

Septo-optic dysplasia (SOD), named by de Morsier in 1956, is a disorder defined by any combination of the classic triad of optic nerve hypoplasia, pituitary dysfunction, and midline brain defects, particularly absence of the septum pellucidum (► Fig. 15.5). There is considerable variation in the phenotype, with fewer than a third of patients having all of the manifestations³³; however, all patients have optic nerve hypoplasia, although the degree of visual impairment and nystagmus is variable. Approximately one-half to two-thirds of patients have an endocrinopathy. Of these, almost all have dysplasia of the hypothalamic–pituitary axis, including a truncated or absent pituitary stalk, a hypoplastic anterior pituitary lobe, and an ectopic or absent posterior pituitary gland.³⁴ Pituitary hormone insufficiency is more frequent in those missing a septum pellucidum than in those with an intact septum. Most patients with SOD are of normal intelligence, but those with developmental delay often have additional brain malformations, including cortical dysplasia and schizencephaly, and they are diagnosed as having SOD+.^{35,36} However, when schizencephaly or polymicrogyria is present, the child typically has minimal or no pituitary dysfunction.³⁷

The management of children with SOD includes the early detection and replacement of deficient pituitary hormones. Although the etiology of SOD remains unclear, maternal diabetes mellitus, cytomegalovirus infection, and exposure to toxins and mutations in four key genes have been implicated: *HESX1*, *SOX2*, *SOX3*, and *OTX2*. Abnormalities in the interplay between these key regulators at the prechiasmatic plate during development determine, in part, the severity of midline brain maldevelopment.³⁸

15.1.7 Dysgenesis of the Corpus Callosum

Agenesis of the corpus callosum (ACC), like SOD and HPE, is a disorder of midline development. It occurs commonly, affecting 0.7% of the general population and 2.3% of the developmentally disabled population.^{39,40} It has a prevalence of between 1 in 4,000 and 1 in 5,000 live births.⁴¹ It can occur in isolation or concurrently with other CNS malformations and is a feature in more than 20 malformation syndromes (see box “Disorders Associated with Agenesis of the Corpus Callosum (p.175)”). In all circumstances, the common pathogenesis is the failure of cortical cells to grow axons across the midline. Failure to develop the dorsal portion of the rostral wall of the midline prosencephalon starting in the middle of the second month of gestation prevents the formation of the commissural plate through which callosal fibers cross the midline. Axons that would normally form the corpus callosum are diverted, forming longitudinal bundles of Probst in a location superior and medial to the lateral ventricles (see box “Magnetic Resonance Imaging Findings of Agenesis of the Corpus Callosum (p.177)”).⁴² Disruption of the migration and differentiation of callosal neurons, impairment of the molecular control of axon growth (e.g., DCC and L1 adhesion molecule), or loss of the guidance of axons traversing the midline by chemoattractants (e.g., netrin 1 and Slit protein) also lead to ACC, but Probst bundles are characteristically absent.⁴³ This often occurs in lissencephaly with ACC (e.g., Walker-Warburg syndrome).

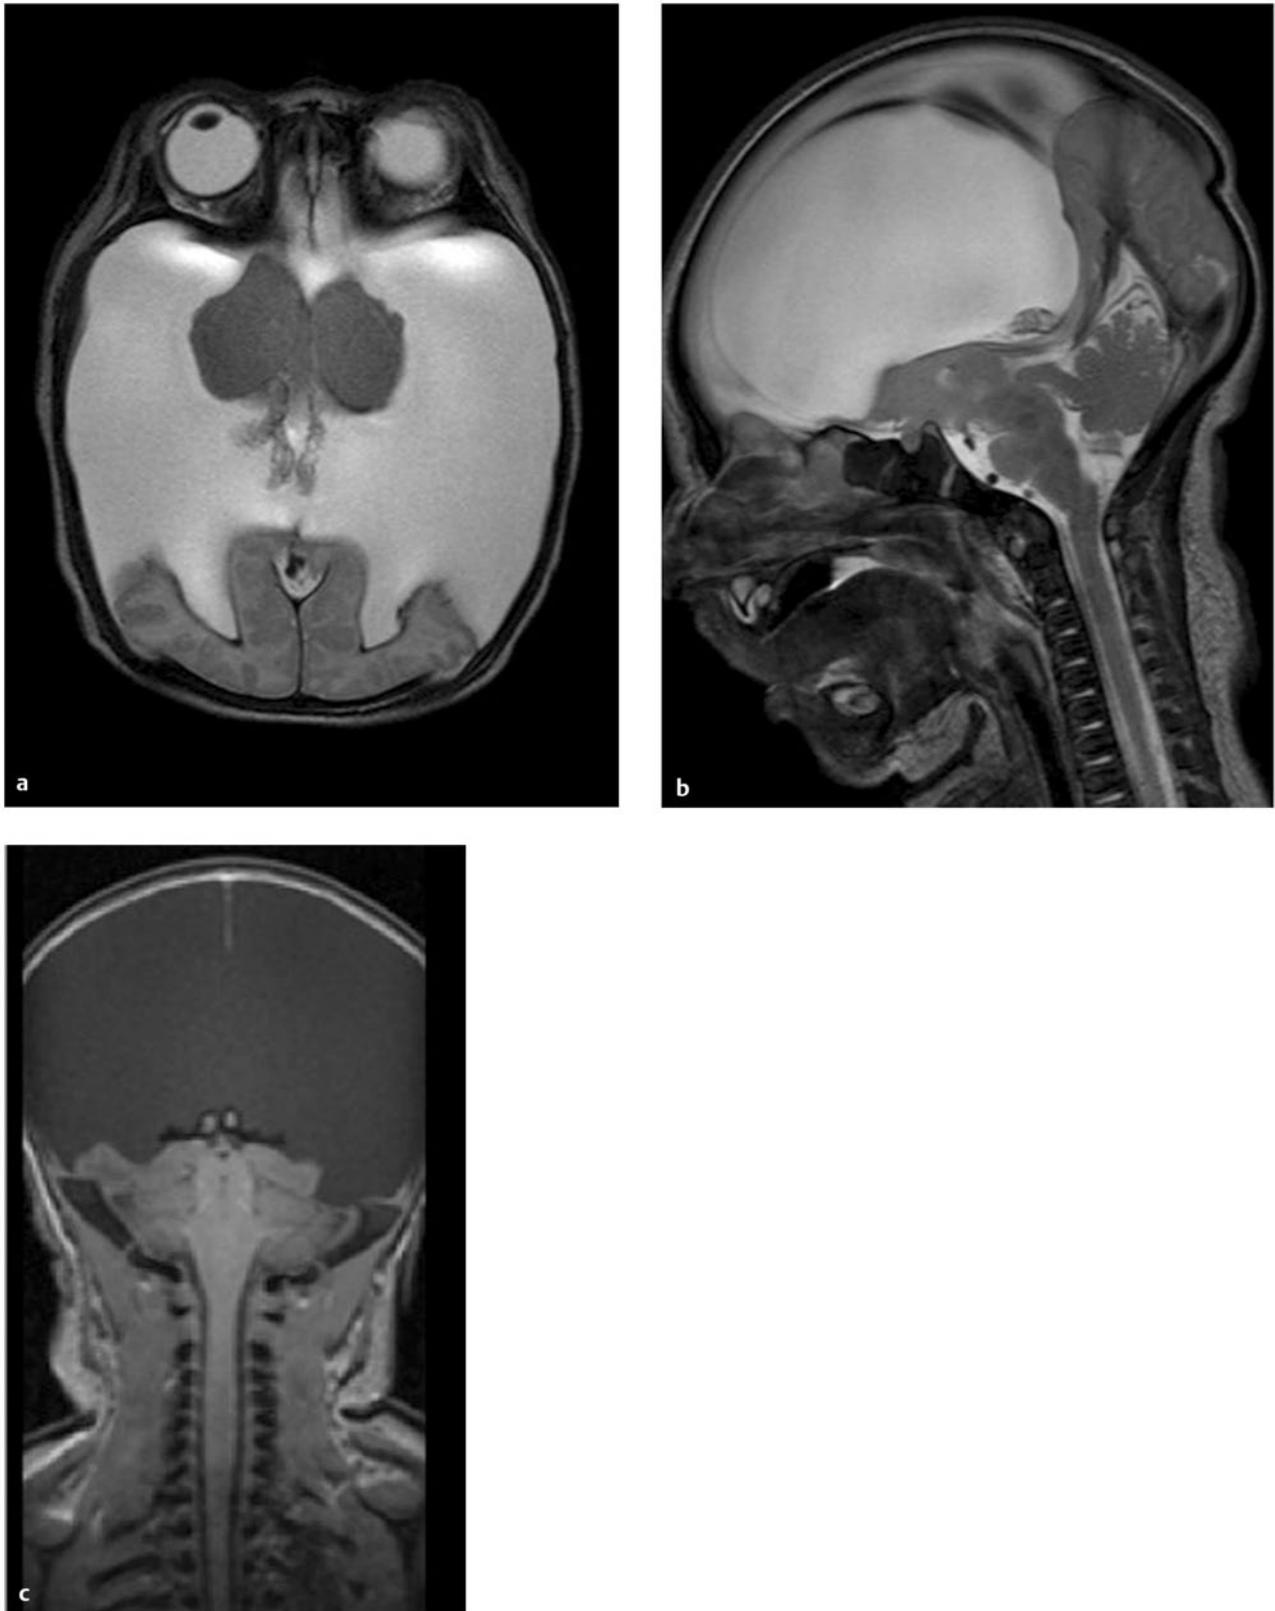

Fig. 15.4 Gradient-echo axial (a) and sagittal T2-weighted (b) and coronal T1-weighted (c) magnetic resonance images of child with hydranencephaly. The cerebral hemispheres, except for a thin rim of the occipital cortex, are absent and replaced by cerebrospinal fluid. The thalamus, brainstem, and cerebellum are preserved. Unlike in HPE, the falx is fully formed.

Disorders Associated with Agenesis of the Corpus Callosum

- Always present
 - Aicardi syndrome
 - Andermann syndrome
 - L1 disease
 - Mowat-Wilson syndrome
 - Chiari type 2 malformation
- Occasionally present
 - Holoprosencephaly
 - Septo-optic dysplasia
 - Dandy-Walker malformation
 - Lissencephaly (Walker-Warburg syndrome, Miller-Dieker syndrome)
 - Other disorders of neuronal migration
 - Fetal alcohol syndrome
 - Metabolic disorders
 - Trisomies 8, 13, and 18

Magnetic Resonance Imaging Findings of Agenesis of the Corpus Callosum

- Separation and parallel orientation of the lateral ventricles
- Radial orientation of the interhemispheric gyri
- Colpocephaly (dilated occipital ventricular horns)
- Probst bundles
- Inversion of the hippocampi
- Absent septum pellucidum
- Rostral extension of the third ventricle
- Hypoplastic or enlarged anterior commissure
- Azygous or wandering anterior cerebral artery
- Absent cingulate sulci with everted cingulate gyri

In partial ACC, the commissural plate is formed, but an arrest of the developing commissure between weeks 7 and 20 of gestation results in an incomplete corpus callosum⁴⁴ (► Fig. 15.6). Typically, the posterior body, splenium, inferior genu, and rostrum of the corpus callosum are missing because they are thought to develop last. However, dysgenesis of the anterior body, genu, and rostrum with a normal splenium has been observed, particularly with semilobar HPE.⁴⁵ This finding suggests that the growth of the corpus callosum is bidirectional instead of anterior to posterior, as has been widely accepted in the past. Lipomas, arising from the remnant of the meninx primitiva, can also prevent full growth of the corpus callosum by mechanical obstruction of the crossing axons.^{46,47}

ACC can sometimes be accompanied by interhemispheric cysts. Barkovich et al classified the cysts as type 1 if they communicate with the lateral or third ventricle and as type 2 if they do not.⁴⁸ They are further divided depending on whether they are associated with hydrocephalus and/or other cerebral abnormalities, such as diencephalic malformation, heterotopia, and polymicrogyria. Except for the subgroup associated with Aicardi syndrome, ACC with interhemispheric cysts is seen predominantly in boys. The cysts are thought likely to be arachnoid, ependymal, or neuroepithelial, but their cause is still indeterminate.

Fig. 15.5 Coronal T1-weighted magnetic resonance image of septo-optic dysplasia shows absence of the septum pellucidum and a hypoplastic optic chiasm (arrow). The frontal horns of the lateral ventricles have a characteristic horizontal roof.

Most children with isolated dysgenesis of the corpus callosum have only subtle neuropsychological deficits because of compensation by the anterior and hippocampal commissures, strengthening of the ipsilateral tracts, and possible bilateral representation of functions.^{41,44} Approximately 15% of patients with isolated ACC have cognitive deficits and psychological disorders, in addition to seizures and hydrocephalus. The morbidity of ACC is related to the associated intracranial anomalies and genetic syndromes.^{47,49}

15.1.8 Microcephaly

Microcephaly is a clinical finding defined as a head circumference that is 2 or more standard deviations below the age- and sex-matched mean. Children with microcephaly do not have true dysmorphic facial features, but the small cranium creates the appearance of a sloping forehead and prominent ears. The small head reflects an undersized brain with a decreased number of neurons related to a decreased number of neural progenitors, decreased proliferation of neurons, or excess death of the progenitors and neurons.^{50,51} Environmental causes include congenital infections (e.g., rubella and cytomegalovirus infection); intrauterine exposure to teratogens (e.g., irradiation, alcohol, and cocaine); and intrauterine growth restriction. Microcephaly is also a feature of many other brain malformations, such as lissencephaly and HPE, and of metabolic disorders. When secondary causes of microcephaly and the presence of other cerebral and extracerebral malformations are excluded, the children are then described as having either microcephaly vera (MV) or microcephaly

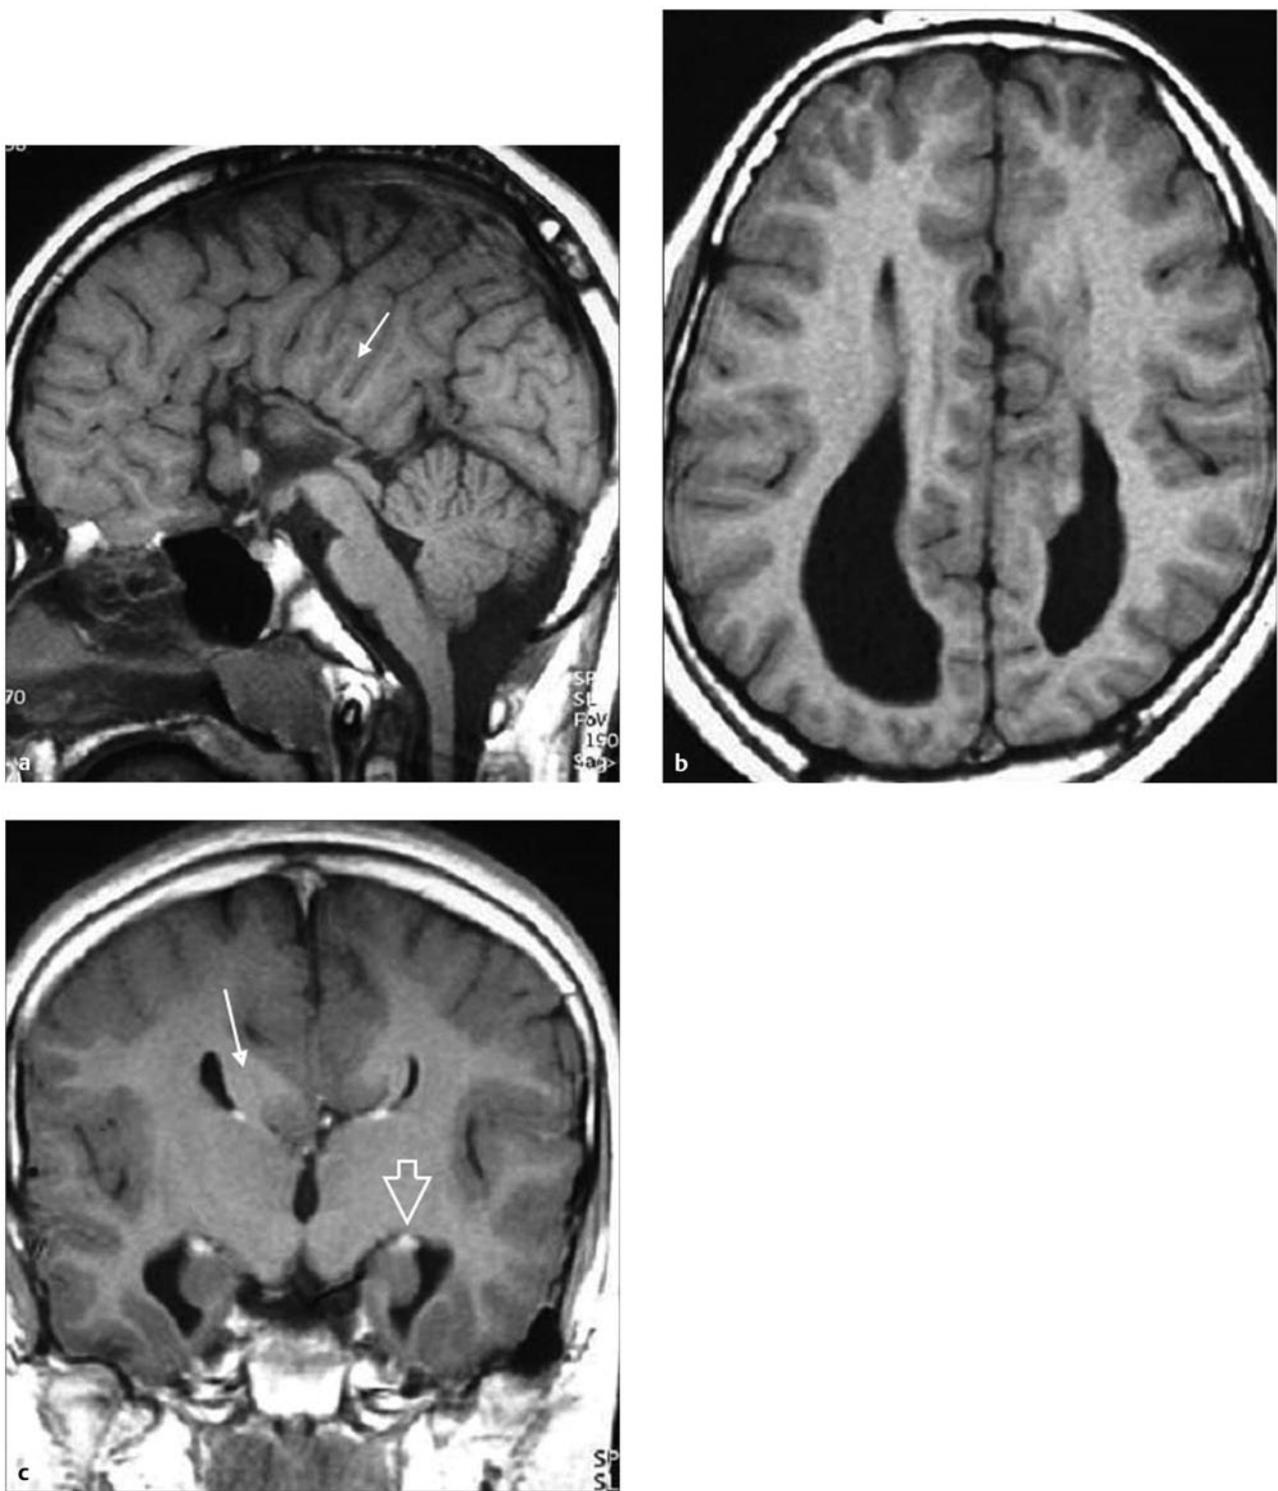

Fig. 15.6 Dysgenesis of the corpus callosum. (a) Midsagittal T1-weighted magnetic resonance (MR) image shows absence of the body, splenium, and rostrum of the corpus callosum. The interhemispheric gyri are oriented radially (*arrow*). (b) Axial T1-weighted MR image shows widely separated and parallel lateral ventricles. The frontal horns are pointed and the occipital horns dilated (colpocephaly). (c) Coronal T1-weighted MR image shows agenesis of the corpus callosum and Probst bundle (*arrow*) indenting the medial surface of the lateral ventricles, resembling a “moose head.” Associated malformations include vertical orientation of the hippocampus (*open arrow*) and distortion of the temporal horn.

with simplified gyral pattern (MSG). The two likely represent a continuous phenotype.

In MV, or “true” microcephaly, the small brain has a normal gyral pattern. The cortical mantle has the normal six layers, but it can be reduced in thickness, with a depletion of neurons in layers 2 and 3.^{50,51} MV has been attributed to faulty proliferation in the germinal zone before the 26th week of gestation, leading to exhaustion of the neuronal pool.⁵² Defects at multiple chromosomal loci, including the genes *MCPH1*, *ASPM* (*MCPH5*), and *SLC25A19*, have been identified and are transmitted in an autosomal-recessive manner.⁵¹ These children have intellectual disability that varies from mild to moderate. Seizures are uncommon, and the life span of patients with mild cases is often normal.

MSG carries a worse prognosis than MV. The child invariably has neonatal seizures, has moderate to severe intellectual disability, and often develops diffuse spasticity.^{53,54} Severe forms of MSG are lethal in infancy. Pathologic findings include a simplified gyral formation, but unlike in lissencephaly, the cortex is not thickened and has normal lamination. When thickening and dyslamination of the cortex are present, the diagnosis of microlissencephaly is given.⁵⁵ MSG and microlissencephaly are possibly the result of a disruption of migration, as well as abnormal proliferation. Like MV, MSG is probably caused by defects of multiple genes transmitted in an autosomal-recessive manner.

15.1.9 Megalencephaly

Megalencephaly is defined as a brain volume greater than 2 standard deviations above the mean. Some authors suggest stricter criteria and include only patients with an occipito-frontal head circumference exceeding the mean by 2.5 standard deviations or the 98th percentile curve by 1 cm or more, but with normal ventricles and extracerebral space.⁵⁶ Depending on the etiology, megalencephaly is described as anatomical or metabolic and is easily differentiated by the history and physical examination. Children with metabolic megalencephaly are born with a normal head circumference, which rapidly increases in girth during infancy from the brain cells' accumulation of undegraded metabolic substrates or aberrant myelin due to a lysosomal deficiency or a dysmyelination syndrome.⁵⁷ Consequently, the children develop progressive neurologic deterioration with signs and symptoms of elevated intracranial pressure (ICP). A thorough family history often reveals autosomal-recessive or X-linked-recessive inheritance.⁵⁸ Examples of causes of metabolic megalencephaly are the gangliosidoses, mucopolysaccharidoses, sphingolipidoses, maple syrup urine disease, Alexander disease, and Canavan disease.

On the other hand, children with anatomical megalencephaly have normal ICP. The girth of the head, which may already be enlarged at birth, increases rapidly within first few months of life and then runs above, but parallel to, the 98th percentile curve.⁵⁸ Almost all anatomical megalencephalies are inherited in an autosomal-dominant pattern. Some patients will have cutaneous stigmata and dysmorphic features consistent with certain neurocutaneous syndromes (e.g., neurofibromatosis and tuberous sclerosis) or rare growth disturbance disorders (e.g., achondroplasia).⁵⁶ Cases without an

etiology or associated syndrome are called primary or familial megalencephaly. These children have normal intelligence and neurologic examinations, and they often have relatives with large heads who are otherwise also normal.⁵⁹ Although all the megalencephalies are classified by Barkovich et al as disorders of the proliferation of normal cells, there are no reported histologic studies of primary megalencephaly, and its embryogenesis is not known.⁶⁰ Previous reports describing intellectual disability, epilepsy, paresis, and the presence of large cortical cells could be due to the grouping of all causes of megalencephaly together and confusion with hemimegalencephaly.^{56–58,61}

15.1.10 Hemimegalencephaly

The clinical findings and prognoses of hemimegalencephaly are notably different from those of megalencephaly. There is marked asymmetry of the hemispheres in hemimegalencephaly, with the affected side enlarged and the opposite side slightly smaller than normal, resulting in varying degrees of midline shift (► Fig. 15.7). Occasionally, the ipsilateral cerebellum and brainstem are also increased in volume.⁶² Computed tomography (CT) and magnetic resonance (MR) imaging show ventriculomegaly with straightening of the frontal horns and colpocephaly in the affected hemisphere (► Fig. 15.8).⁶³ The cerebrum is often lissencephalic, but polymicrogyria, gray matter heterotopia, focal cortical dysplasias, and rarely

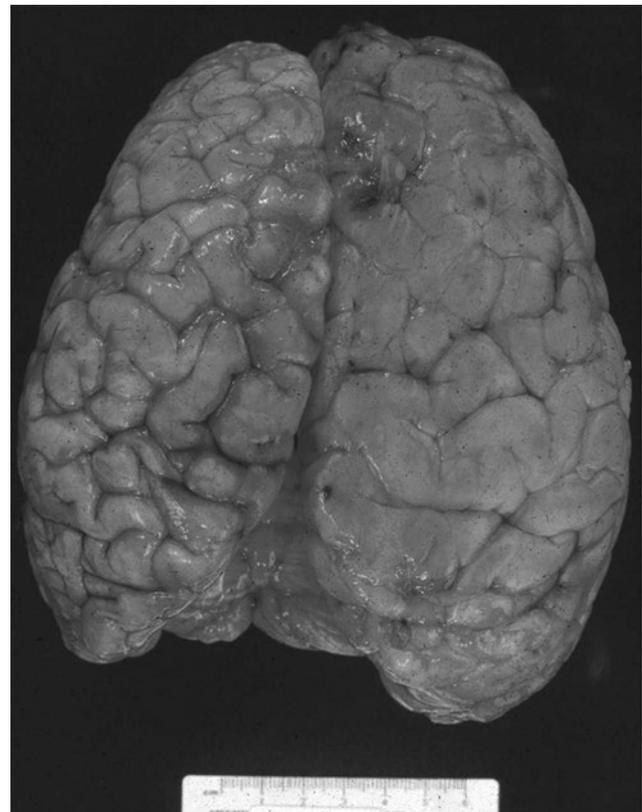

Fig. 15.7 Vertex view of the gross pathology of hemimegalencephaly. The entire right hemisphere is enlarged and has pachygyria and shallow sulci.

Fig. 15.8 Axial T1-weighted image of a child with hemimegalencephaly. The overgrown right hemisphere has an enlarged lateral ventricle, thickened cortex with a poor gray–white matter junction, and primitive veins in the sylvian fissure (*arrow*). There is diffuse loss of sulci in both hemispheres.

schizencephaly and ACC may also be seen. The cortex is thickened and is indistinct from the underlying white matter, which is often hyperintense on a T2-weighted MR image.

Histologic examination of the corresponding cerebrum reveals disruption of cortical lamination, a poor gray–white matter border, and abundant hypertrophic neurons and balloon cells positioned throughout the gray and white matter.⁶⁴ Both cell types are immunoreactive to glial and/or neuronal proteins. Many authors have concluded that hemimegalencephaly is a disorder of cellular lineage, neuronal migration, and/or genetic regulation of body symmetry.^{63,65} However, the etiology is still uncertain, and there is no known genetic mutation or familial inheritance. Hemimegalencephaly with neurocutaneous disorders has a similar neurologic picture, pathologic features, MR imaging findings, and electroencephalographic abnormalities.⁶³

The child with hemimegalencephaly typically presents with cranial asymmetry, hemiplegia, and intractable seizures that start soon after birth. Partial seizures occur most frequently, followed by tonic seizures and infantile spasms.⁶³ The best chance for seizure control and improvement of neurologic and psychomotor development is with early hemispherectomy or hemispherotomy.⁶⁴ Children with the early onset of neurologic symptoms demonstrate severe retardation of global development and an increased risk for mortality during infancy.⁶³ At the other end of the spectrum, those with mild hemimegalencephaly may have only subtle deficits and a normal life expectancy.

15.1.11 Focal Cortical Dysplasia

Focal cortical dysplasias (FCDs) are localized areas of malformed cerebral cortex that are frequently associated with epilepsy. Taylor et al were the first to describe FCDs and their association with nonfamilial, nonsyndromic refractory epilepsy.⁶⁶ A broad spectrum of histopathology is seen in the diagnosis of FCD. Currently, a three-tiered classification system is used to characterize specific clinicopathologic FCDs.⁶⁷ Type 1 FCDs are isolated lesions that present as radial (FCD type 1a) or tangential (FCD type 1b) dyslamination of the neocortex, microscopically identified in one or multiple lobes. Type 2 FCD is an isolated lesion characterized by cortical dyslamination and dysmorphic neurons without (type 2a) or with (type 2b) balloon cells. Type 3 FCD occurs in combination with hippocampal sclerosis (FCD type 3a) or epilepsy-associated tumors (FCD type 3b), or adjacent to vascular malformations (type 3c) or epileptogenic lesions acquired in early life (type 3d), such as traumatic injury, ischemic injury, and encephalitis. The dysplasias can be localized to any part of the cerebrum but are frequently found at the frontal and temporal lobes.⁶⁸

Type 2 FCD, with or without balloon cells, is usually visible on MR imaging, is highly epileptogenic, and has the lowest operative success rate. MR imaging findings include cortical thickening, poor delineation of the gray–white matter junction, and increased signal of the cortex and underlying white matter.⁶⁹ Type 1 FCD is typically not visible on MR imaging but has better surgical outcomes than lesions with dysmorphic neurons.⁷⁰ Besides the histologic composition, the seizure-free success rate is determined by the extent of resection.

The pathogenesis of FCD is not clear but may occur during cell proliferation, neuroblast migration and differentiation, and/or cortical organization.⁶⁸ The tubers of tuberous sclerosis and cortices of hemimegalencephaly also contain balloon cells and are thus often grouped together with FCD.⁷¹

15.1.12 Congenital Neoplasms

Even though congenital neoplasms are classified under the heading of abnormal proliferation, their etiology is likely multifactorial, as is the case with postnatal-onset tumors. Particular to the developing brain, however, is its susceptibility to neoplastic transformation by genetic mutation and teratogens because of rapid cellular proliferation.⁷² Alterations of the regulatory cues for cell proliferation, differentiation, and apoptosis have the potential to result in neoplastic growth because many oncogenes and tumor suppressor genes involved in cancers are also regulators of normal CNS development.^{73,74} The finding of increased risk for pediatric brain tumors when there is a maternal family history of birth defects suggests either that malformations and neoplasia share a common etiology or that malformations confer a susceptibility for neoplastic transformation during childhood.^{75,76} Yachnis et al found that the granule cells that comprise vermian dysplasias are mitotically active after birth.⁷⁷ These granule cells are therefore potential precursors of cerebellar tumors. Pediatric supratentorial tumors (e.g., ganglioglioma, dysembryoplastic neuroepithelial tumor, and pleomorphic xanthoastrocytoma) have also been linked to, or have been observed to develop from, cortical dysplasias.^{78–81}

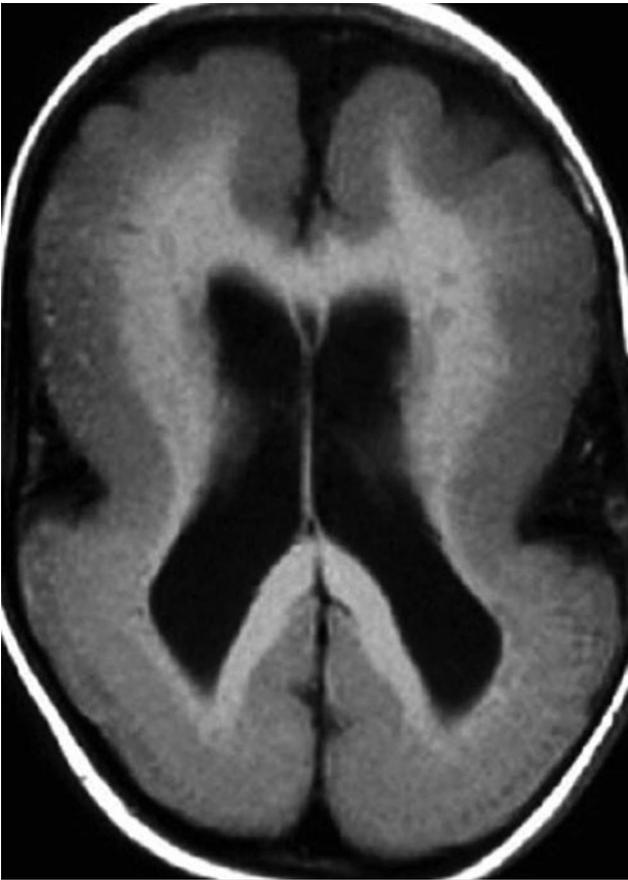

Fig. 15.9 Axial T1-weighted magnetic resonance image of classic lissencephaly (type 1) shows a smooth cortical surface with minimal gyri and sulci at the frontal lobes. The shallow sylvian fissures give the brain an "hourglass" configuration.

15.1.13 Lissencephaly

Lissencephaly is a diffuse bihemispheric abnormality that occurs in approximately 12 of every 1 million births and is characterized by a smooth or nearly smooth cortical surface (► Fig. 15.9).^{39,82} It is a disorder of neuronal migration, ranging in severity from the complete absence of convolutions (agyria) to a regional decrease in sulcation resulting in broad gyri (pachygyria). Lissencephaly is characterized by a cerebral cortex that is thickened to 10 to 20 mm (normal is 2.5 to 4 mm) and has four layers instead of six.^{83,84} Subcortical band heterotopia (SBH) is considered a mild form of lissencephaly in which bands of gray matter of varying width become embedded in the white matter and parallel the cortex of both hemispheres (► Fig. 15.10).

Lissencephaly can be classified genetically on the basis of genes involved in neuronal migration that, when mutated, result in lissencephaly. Classic lissencephaly (previously described as type 1) is associated with deletions of the *LIS1* gene on chromosome 17p13 and the *DCX* (also known as *XLIS*) gene on chromosome Xq.^{85,86} Both genes regulate microtubule formation and activity during neuronal migration. The tubulin- α 1a gene (*TUBA1A*), like *LIS1* and *DCX*, encodes a microtubule-related protein and has recently been implicated in the pathogenesis of

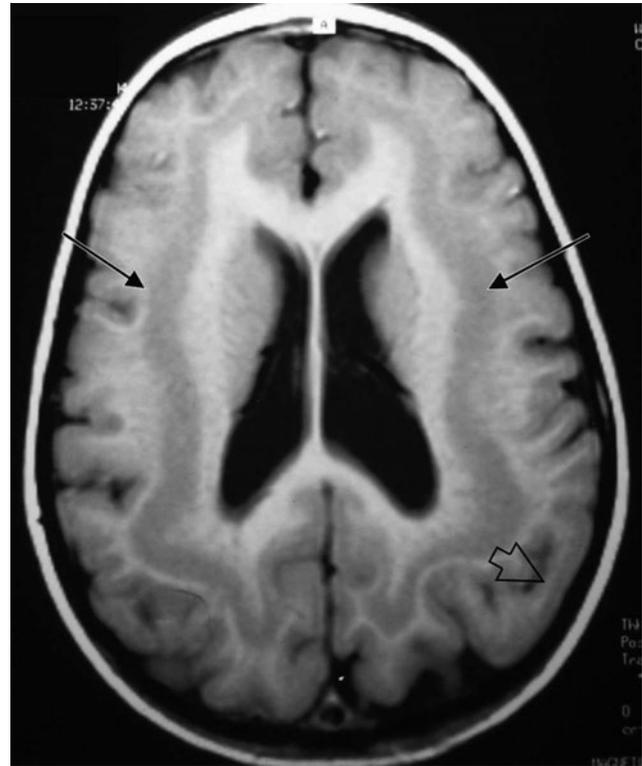

Fig. 15.10 Axial T1-weighted magnetic resonance image of a child with subcortical band heterotopia (double cortex). The bands of gray matter are situated between the lateral ventricles and cerebral cortex (arrows). Note the associated pachygyria (open arrow).

lissencephaly.⁸⁶ Large deletions of *LIS1* and the contiguous gene *14-3-3 ϵ* are associated with Miller-Dieker syndrome, which is characterized by lissencephaly with dysmorphic facial features.^{39,82} Patients with classic lissencephaly, on the other hand, have no other abnormalities, including those of the face. Mutations of *DCX* also cause isolated lissencephaly in males, but heterozygous females develop SBH.⁸³ The frontal lobes of patients with *DCX* mutations are affected more than the occipital lobes, and the opposite is true in patients with *LIS1* mutations.

Lissencephaly plus ACC occurs with mutation of the *ARX* gene located on chromosome Xp22.13 and is associated with underdevelopment of the genitalia.⁸³ Patients who have lissencephaly with mutations of the *RELN* gene manifest malformations of the hippocampus and a severely hypoplastic cerebellum.⁸³ Little is known about the genetics of microlissencephaly, which is characterized by a severely microcephalic brain with diffuse decreased sulci and cerebellar hypoplasia.⁵⁴

Children with classic lissencephaly have a normal head size at birth, but their head growth plateaus, resulting in microcephaly within the first year.⁸² They are often intellectually disabled, have early-onset seizures, and exhibit hypotonia that shifts to hypertonia. The age at onset, severity of seizures, and degree of cognitive dysfunction depend upon the lobes of the brain involved and the volume and extent of misplaced gray matter.⁸² Treatment entails providing adequate nutrition, managing aspiration episodes, and controlling seizures. The majority of patients die within 10 years of aspiration pneumonia and sepsis.

15.1.14 Cobblestone Complex

Cobblestone dysplasia is a disorder of glycosylation that results in cortical dysplasia and dysmyelination, dysplastic cerebellum with cysts, and brainstem hypoplasia.⁸⁷ Previously classified as lissencephaly type 2, because of the grossly smooth surface of the involved cortex, cobblestone dysplasia has now been re-categorized since its mechanism of malformation was elucidated. In contrast to lissencephaly, in which the neurons fail to reach the cortical plate, in cobblestone dysplasia, the neurons pass through the cortex into the subpial space and appear on the brain surface like cobblestones.^{83,87} The cortex is thick, as it is in lissencephaly, but cortical lamination is not evident. Moore et al discovered that failure to glycosylate the dystroglycan results in breaches in the glia limitans, the pial surface lamina, allowing migrating neurons to exit the brain proper.⁸⁸

Loss of dystroglycan function may underlie the cobblestone dysplasia observed in at least three genetic disorders: Walker-Warburg syndrome, Fukuyama-type congenital muscular dystrophy, and muscle–eye–brain disease.⁸⁹ Children born with these congenital muscular dystrophies have profound neonatal hypotonia, ophthalmologic malformations, and cerebellar dysplasia.⁸³ Patients may die at infancy or live to adulthood without significant morbidity depending on the severity of weakness, seizures, and intellectual disability and on the type of muscular dystrophy.

15.1.15 Gray Matter Heterotopia

Neuronal heterotopias are disorders of neuronal migration that result in collections of normal neurons situated anywhere between the germinal zones and the subcortical white matter.⁹⁰ Normal neural migration entails attachment of neurons to radial glial cells and migration along the glial cells, followed by detachment at the appropriate cortical layer. Interruption of this basic process along various points results in the heterogeneous appearances of the neuronal heterotopias.⁸³ Barkovich et al grouped heterotopias into three categories: periventricular (subependymal), subcortical (other than band heterotopia), and marginal glioneuronal heterotopia.⁶⁰

Periventricular heterotopia is characterized by nodular masses of gray matter lining the lateral ventricles and protruding into the ventricular spaces (► Fig. 15.11). Bilateral periventricular nodular heterotopia may be X-linked, and therefore familial, while unilateral subependymal heterotopia and sparsely scattered subependymal heterotopia present sporadically.⁹¹ When it is X-linked, bilateral periventricular nodular heterotopia is more prevalent in females because of its lethality in males. Bilateral periventricular nodular heterotopia results from a defect in the filamin A (also known as filamin-1) gene (*FLNA*), which is needed for linking actin filaments to glycoproteins and is essential to the process of neuronal migration.^{92,93} Ninety percent of these patients have epilepsy, and many have intractable seizures.³⁹ Females who are heterozygous for the mutation have epilepsy, which varies in severity, and have borderline to normal intelligence. Patients who have periventricular heterotopias are more likely to demonstrate normal development in comparison with those who have other types of heterotopia.

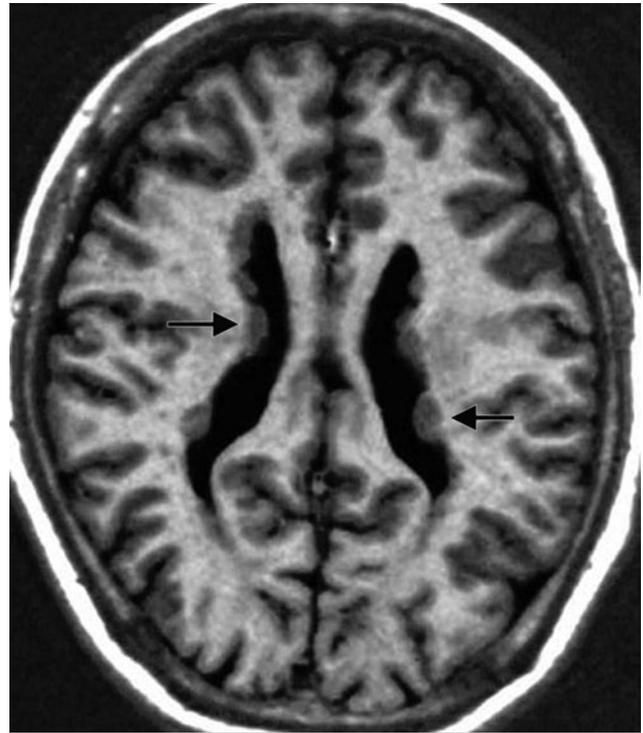

Fig. 15.11 Axial T1-weighted magnetic resonance image of bilateral periventricular nodular heterotopia shows gray matter lining and indenting the lateral ventricles (arrows).

Subcortical heterotopia has three different forms, each with its own pattern of ectopic tissue: multiple nodules, curvilinear ribbons, and a mixture of deep nodular regions with curvilinear areas in the periphery⁹⁴ (► Fig. 15.12). Patients with subcortical heterotopias have weakness, spasticity, hyperreflexia, and seizure onset within the first decade of life. Marginal glioneuronal heterotopia carries the worst prognosis of the three categories; patients have severe developmental delay, early onset of seizures, and a low survival rate past the age of 1 year.⁹⁵ The pathology shows neurons breaching the neuropial border and causing damage and fusion of the normal barriers between cortical convolutions.

Except for those with marginal glioneuronal heterotopia, most patients with heterotopia are asymptomatic and of normal intelligence. In general, larger masses of heterotopic tissue result in a more severe clinical picture.⁹⁶ In severe cases, patients can develop infantile spasms, Lennox-Gastaut syndrome, motor impairment, and intellectual disability. The management of neuronal heterotopias centers largely on control of seizures with antiepileptic drugs. Localized seizure foci that are refractory to medical management may be surgically removed if the seizure focus is amenable to resection. The preoperative imaging characteristics of heterotopia are subtle because the lesions do not enhance and are devoid of calcification.⁹⁷

15.1.16 Schizencephaly

Schizencephaly has often been described as a disorder of neuronal migration resulting in cerebral clefts. It is now

believed that the causes may be heterogeneous, with many cases secondary to vascular disruption.⁹⁰ However, unlike in cases of simple vascular occlusion, the walls of the clefts are lined by abnormal cortex that is typically polymicrogyric, and thus some authors have suggested that schizencephaly is a result of abnormal postmigrational development and should be reclassified as polymicrogyri of disruptive etiology (see box “Classification of Supratentorial Malformations (p.171)”).^{90,96} The defect, typically in the perisylvian region, runs the full thickness of the cortex, from the pial surface to

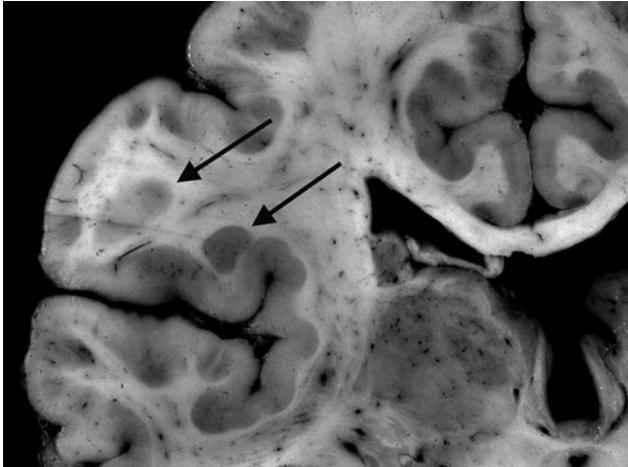

Fig. 15.12 Coronal gross pathology shows small subcortical gray matter heterotopias (arrows) at the frontal operculum with normal overlying cortex.

the ventricular surface, permitting direct communication between the lateral ventricle and the subarachnoid space (► Fig. 15.13). Gyri on the cerebral surface project radially from the cleft and usually contain cortical dysplasias. Schizencephaly is also frequently associated with gray matter heterotopia, absence of the septum pellucidum, ACC, and SOD.^{54,98}

Schizencephalic clefts are described as either open-lipped (walls separated) or closed-lipped (walls apposed) and may present unilaterally or bilaterally. The prognosis is worst for patients with bilateral open-lipped schizencephaly.^{97,98} Patients with a unilateral closed-lipped defect have hemiparesis but mild or no cognitive deficits, whereas those with bilateral clefts present with severe developmental delays, microcephaly, hydrocephalus, and spastic tetraparesis. Eighty percent of patients develop epilepsy, most commonly focal seizures.³⁹ Patients with open-lipped schizencephaly have an earlier onset of seizures than do those with closed-lipped schizencephaly; seizures typically start by the age of 3 years.

Genetic mutations and antenatal insults, such as toxic or infectious exposures or vascular compromise, have been implicated in schizencephaly.⁹⁸ Granata et al reported mutations of the *EMX2* gene on chromosome 10q26.1 in their patients with open-lipped schizencephaly.⁹⁹ *EMX2* is expressed by proliferating neuroblasts in the ventricular zone and is responsible for both patterning of the forebrain structure and neuronal migration. However, since first described, mutations of the *EMX2* gene have not been detected in familial cases, suggesting that multiple chromosomal loci are likely involved in the pathogenesis of schizencephaly.^{100,101}

The walls of the transmantle cleft are apposed and lined by gray matter (arrows). Note the deformity in the lateral ventricle, where the ependyma is continuous with the cleft (open arrow). (b) Coronal T1-weighted magnetic resonance image of another child shows gray matter (arrows) lining a left unilateral open-lip cleft.

15.1.17 Porencephaly

Porencephaly, which can be confused with schizencephaly, is lined by gliotic white matter as opposed to dysplastic gray matter. Porencephalic cysts are not malformations. Instead, they are thought to be due to fetal or perinatal intracranial hemorrhage and strokes that result in transmantle destruction of the brain.^{32,102} Maternal and fetal risk factors include cocaine abuse, blood dyscrasias, trauma, and alloimmune thrombocytopenia.

15.1.18 Polymicrogyria

Polymicrogyria is a malformation of cortical development occurring near the end of neuronal migration and during early cortical organization when neurite extension, synaptogenesis, and neuronal maturation normally occur.⁸³ It is categorized as an abnormality of postmigrational development.⁹⁰

Afflicted brain cortices have excessively numerous, small gyri separated by shallow sulci (► Fig. 15.14). The increased number of convolutions results in the appearance of an abnormally thick cortex. Polymicrogyria has traditionally been described as “four-layered” or “unlayered” if there is complete loss of cortical lamination. However, polymicrogyria likely exists as a continuum because the two histologic patterns, and occasionally double- or triple-layered cortices, can occur within the same patient.¹⁰³ These cortical malformations can be focal or widespread and unilateral or bilateral.

Fig. 15.14 Axial T2-weighted magnetic resonance image of polymicrogyria shows an excessive number of small gyri (arrows) at the left temporal lobe and opercular cortex.

Polymicrogyria often coexists with other developmental brain anomalies and is present in most cases of schizencephaly. Most cases of polymicrogyria are sporadic, some of them associated with intrauterine cytomegalovirus infection or compromised placental perfusion.¹⁰⁴ Studies of familial cases indicate that polymicrogyria is genetically heterogeneous and exhibits various patterns of inheritance. Polymicrogyria can be syndromic, especially when it occurs symmetrically in the two hemispheres. In these syndromes, the topology of the affected brain is discrete and consistent, and the clinical symptoms are predictable because they are comparable in similarly affected patients. The most common and best described of these syndromes involves the bilateral perisylvian cortex. Affected individuals have cognitive impairment, epilepsy, and pseudobulbar signs, including dysarthria and dysphagia.^{105,106} Bilateral perisylvian polymicrogyria has an X-linked locus that maps to Xq28, although some patients demonstrate deletions of 22q11.2.

MR imaging of polymicrogyria reveals small irregular gyri, normal or thickened cortices, and an indistinct cortical–white matter junction.¹⁰⁴ In isolated polymicrogyria, the patient’s signs and symptoms correlate with the area of the brain affected. The prognosis varies depending on the extent and location of the malformation, with the sequelae being as minimal as a discrete neurologic impairment or as severe as encephalopathy with intractable seizures.³⁹

15.1.19 Joubert Syndrome

In 1968, Joubert et al were the first to describe a clinical syndrome of alternating hyperpnea and apnea, ataxia, oculomotor apraxia, muscle hypotonia, and intellectual disability in four siblings of consanguineous parents.^{107,108} Subsequent studies of patients with Joubert syndrome describe mid-brain–hindbrain malformation, dysgenesis of the vermis, and fragmentation and hypoplasia of brainstem nuclei and tracts.¹⁰⁹ Affected neonates have a characteristically large head with a prominent forehead, high rounded eyebrows, epicanthal folds, ptosis, a turned-up nose, and a tongue that protrudes irregularly through an open mouth.¹¹⁰ Later in infancy, the children sometimes exhibit behavioral problems, such as separation anxiety, noise hypersensitivity, crying jags, and aggressive behavior.

A deep interpeduncular fossa, elongated and thick superior cerebellar peduncles oriented perpendicularly to the brainstem, and an absent or hypoplastic vermis together give the appearance of a molar tooth on axial-view MR imaging¹¹⁰ (► Fig. 15.15). The MR image may also reveal a cleft vermis with a small dysplastic anterior lobe and an absent posterior lobe. Although the molar tooth sign is most often seen with Joubert syndrome, it is present in other related syndromes, including Dekaban-Arima syndrome, Senior-Löken syndrome, COACH (cerebellar vermis hypoplasia, oligophrenia, congenital ataxia, coloboma, hepatic fibrosis), Váradi-Papp syndrome, Malta syndrome, Joubert plus retinal dystrophy, and Joubert plus

polymicrogyria.^{111,112} Patients with the related syndromes manifest the classic clinical signs of Joubert syndrome plus various combinations of other distinct features: polymicrogyria, encephalocele, coloboma, hepatic fibrosis, nephronophthisis, polydactyly, renal cysts, retinal dystrophy, and tongue tumors. There is wide phenotypic variability, even among family members, and thus the splitting of Joubert syndrome into other disorders is controversial.

The malformation of the midbrain, upper hindbrain, and cerebellum is thought to evolve from improper patterning of the mesencephalon and metencephalon by the isthmus organizer located at the midbrain–hindbrain boundary.^{109,113} The replacement of genes involved in the development of the isthmus organizer and midbrain–hindbrain patterning in knockout mice causes them to develop malformations similar to those of Joubert syndrome.¹¹⁴ More recent work highlights the role of ciliary defects in the pathogenesis of Joubert syndrome and other ciliopathies such as congenital cerebellar ataxia.¹¹⁵ However, the underlying gene defects resulting in Joubert syndrome are likely heterogeneous. Inheritance is assumed to be autosomal-recessive because of the lack of vertical transmission and increased incidence in children of consanguineous parents.^{110,116}

The prognosis for patients with Joubert syndrome and related disorders is poor. Although some reach the fourth decade of life, the 5-year survival is 50%.^{110,112,116} Survivors suffer cognitive, motor, and visual deficits, as well as other multisystem disorders.¹¹⁰ Survival after infancy dependent upon renal and

hepatic complications, and therefore regular examination by a physician is indicated.

15.1.20 Rhombencephalosynapsis

Rhombencephalosynapsis is a rare malformation first described by Obersteiner in 1916 in a case report entitled *Ein Kleinhirn ohne Wurm*, which is translated as “A Cerebellum without Vermis.” The report detailed the postmortem evaluation of a 31-year-old man.¹¹⁷ This condition is characterized by dorsal fusion of the cerebellar hemispheres with agenesis or severe hypogenesis of the vermis, transversely oriented cerebellar folia, and variable degrees of fusion of the dentate nuclei and middle cerebellar peduncles¹¹⁸ (► Fig. 15.16). The superior cerebellar peduncles, tectum, thalami, and fornices may also be fused. Associated anomalies include hydrocephalus, absent septum pellucidum, fusion of the fornices, HPE, hypoplastic anterior commissure, hypoplastic temporal lobes, gray matter heterotopias, and missing olivary nuclei.^{119–123} Rhombencephalosynapsis can occur in conjunction with two other syndromes, Gómez-López-Hernández syndrome and VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, limb defects).¹²⁴

The pathogenesis is uncertain, but rhombencephalosynapsis may result from improper development of the rhombencephalon at approximately 28 to 45 days of gestation, either from insufficient dorsal induction, defective rhombic lips, or failure of vermian differentiation.^{121,123} More recent studies suggest a

genetic origin, with recurrent cases, parental consanguinity, and diverse chromosomal abnormalities.¹²⁴ The prognosis is highly variable but may be related to the presence of supratentorial anomalies. In cases of isolated rhombencephalosynapsis, patients can have normal cognitive and language function, as did the patient originally described by Obersteiner.^{122,123} Alternatively, patients can have intellectual disability, ataxia, epilepsy, diplegia, and spasticity. Behavioral changes, such as self-mutilation, obsessive-compulsive disorder, and stereotyped “head-rolling” movements, have been reported.¹²⁵ Surgery is needed only for symptomatic hydrocephalus.

15.1.21 Lhermitte-Duclos Disease

Lhermitte-Duclos disease (LDD), also known as dysplastic cerebellar gangliocytoma, is a rare disorder of the cerebellar cortex first described by Lhermitte and Duclos in 1920.¹²⁶ In the more than 150 cases reported since that time, the numbers of males and females are equal. Patients range in age from neonates to the elderly, but many are diagnosed in their third or fourth decade of life.^{127,128} Patients typically present with symptoms consistent with a slowly growing posterior fossa mass. The most frequent complaints associated with LDD are headaches, nausea and vomiting, vertigo, ataxia, gait disturbances, and cranial nerve dysfunction. Additionally, hydrocephalus from compression of the fourth ventricle can cause papilledema, loss of vision, rapid neurologic deterioration, and death.¹²⁷

CT often reveals a fourth ventricle distorted by an iso- or hypodense cerebellar lesion that occasionally contains small areas of calcification. MR imaging of patients with LDD shows a hypointense lesion on T1-weighted images and a characteristic lamination, or “tiger stripe” pattern, composed of thickened cortical folia on T2-weighted images¹²⁷ (► Fig. 15.17). The lesion itself does not enhance after contrast administration; however, proliferating veins within the lesion, as well as the surrounding leptomeninges, can enhance.¹²⁹ The disease usually involves one hemisphere, but it occasionally extends to the vermis or to the contralateral hemisphere.

In LDD, the cerebellar cortex is expanded, and there is a gross reduction of the central white matter. The pale and thickened folia contain hypertrophic granular cells in the internal granular layer that project enlarged and irregularly myelinated axons into the molecular layer.¹³⁰ The Purkinje layer is absent and replaced by granular cells. The presence of ectopic granule neurons in the molecular layer indicates that LDD, in addition to being a disorder of cellular growth, may result from the abnormal inward migration of granule cells from the external granule layer. Some authors have suggested that these cerebellar tumors are neoplastic because of the resemblance of the large granular cells to blastomas, as well as their natural history of growth and possible recurrence after resection.¹³¹ On the other hand, the similar orientation of the enlarged cells to that of normal granule cells, lack of mitotic figures, and low proliferation index underscore their benign character. Recurrence may represent progressive growth of minimally affected regions that appeared normal on MR imaging at the time of initial resection.

The deviant migration and cellular growth in LDD have been linked to germline mutations of the tumor-suppressing phosphatase and tensin (*PTEN*) homologue gene that regulates cell

Fig. 15.17 Axial T2-weighted magnetic resonance image of the posterior fossa of a patient with Lhermitte-Duclos disease shows a hyperintense left cerebellar lesion, with widened folia in a striated pattern, mildly compressing the fourth ventricle.

apoptosis, growth, migration, and differentiation. *PTEN* inactivation results in loss of inhibition of phosphatidylinositol-3-kinase, leading to increased levels of phosphorylated AKT (p-AKT). In turn, p-AKT promotes hypertrophy and survival of the granule cells in LDD via the rapamycin (mTOR) downstream effector.¹²⁸ LDD has been associated with Cowden disease, an autosomal-dominant disorder that also carries germline mutations of *PTEN*.^{127,130} Patients with Cowden disease have mucocutaneous lesions, macrocephaly, systemic hamartomas (including LDD), and neoplasms of the breast, thyroid, genitourinary tract, and endometrium. However, a minority of patients with LDD do not have manifestations of Cowden disease. These are typically children at the time of diagnosis and lack the *PTEN* mutation, despite activation of mTOR.^{128,132}

Although LDD is benign, the definitive treatment is prompt surgical resection because of the mass's propensity to grow. The lack of a sharp border between the tumor and normal cerebellar tissue accounts for a recurrence rate that approaches 30%.¹²⁸ Patients require genetic testing and a thorough search for concomitant neoplastic or hamartomatous lesions associated with Cowden disease. Patients with a diagnosis of LDD require long-term follow-up because of the high risk for recurrence, probable inheritance, and need for the early detection of potential cancers.

15.1.22 Cerebellar Hypoplasia

Hypoplasia of the cerebellum can be isolated to the vermis or diffusely involve the vermis and hemispheres, and it includes the Dandy-Walker malformation. Both forms are heterogeneous conditions and are a feature in a variety of intracranial and extracranial malformation syndromes. Patients with Dandy-Walker malformation characteristically have cystic dilatation of the fourth ventricle and enlargement of the posterior fossa with upward displacement of the tentorium and torcular, in addition to partial or complete agenesis of the vermis. Diffuse cerebellar hypoplasia is associated with ciliopathy; trisomies 13, 18, and 21; granule cell hypoplasia; cerebral and cerebellar migration disorders; and intrauterine exposure to teratogens.^{133,134} Because the cerebellum is also involved with cognitive functions, affected infants develop learning disabilities, as well as motor deficits. In Dandy-Walker malformation, the psychomotor impairment is often potentiated by supratentorial anomalies, including hydrocephalus, which is seen in up to 90% of children, dysgenesis of the corpus callosum, and HPE.^{135,136} Patients with unilateral hemispheric hypoplasia have mild or no symptoms, and it is assumed to be a consequence of a vascular insult, not a malformation.¹²³

Isolated cerebellar vermis hypoplasia also has a favorable prognosis. However, when vermian hypoplasia coexists with cerebral cortical malformations, it either is inherited as an X-linked disorder or is part of a syndrome, and it is associated with severe intellectual disability.^{133,134} On imaging, patients have a hypoplastic but normally positioned vermis and an enlarged fourth ventricle that communicates with a small, retrocerebellar cerebrospinal fluid space. Although cerebellar vermis hypoplasia appears similar to and is often diagnosed as a Dandy-Walker variant, it is thought to be unrelated etiologically to Dandy-Walker malformation.¹³⁶

15.1.23 Pontocerebellar Hypoplasia

Hypoplasia of the cerebellum is common to a variety of disorders. Concomitant mild hypoplasia of the pons will result if there is loss or atrophy of the large transverse fibers between it and the cerebellum. The distinguishing feature of pontocerebellar hypoplasia (PCH), which occurs rarely, is the paucity of pontine neurons. PCH is a devastating condition characterized by multiple structural abnormalities of the pons, dentate, inferior olive, and cerebellum. Disruption of the rhombic lip during cerebellar development is the suspected pathogenesis because the rhombic lip is the source of neuron precursors for the cerebellum and the pons. PCH classifications have evolved over the last 10 years to include seven types at present,¹³⁷ but types 1, 2, and 4 (also known as olivopontocerebellar atrophy, or OPCA) are most frequently described. PCH is an autosomal-recessive disorder with several genes implicated in its pathogenesis, including *TSEN54*, *RARS2*, *CLAM*, and *VRK1*.^{133,134,137}

An infant with PCH type 1 has characteristic degeneration of the spinal anterior horn cells, resembling infantile spinal muscular atrophy, as well as degeneration of the dentate nuclei and neurons of the pons. The defects result in respiratory and swallowing difficulties, central or peripheral motor dysfunction with hypertonia or hypotonia, and muscle contractures. These children often require mechanical ventilation at

birth and all die by the age of 1 year, often of respiratory complications. The hallmark of PCH type 2 is continuous extrapyramidal dyskinesia during waking, which starts as chorea and then evolves to dystonia later in childhood. The child does not exhibit any cognitive or motor development but has an early onset of seizures. Microcephaly results from progressive atrophy of the cerebrum. The dominant symptoms of PCH type 4 are cerebellar, including disequilibrium, ataxia, and dysarthria, and do not clinically manifest until youth or the middle years.¹³⁸ MR images of the brain in patients with PCH types 1, 2, and 4 are similar: cerebellar hemispheres that are reduced to winglike structures positioned just below the tentorium, a hypoplastic vermis with all lobes preserved, and absence of a pontine bulge (► Fig. 15.18).

15.2 Fetal Imaging

Early in utero diagnosis of congenital anomalies guides the parents' decision concerning the continuation of pregnancy and the physicians' plans for possible fetal surgery, mode of delivery, and postpartum care. Fetal ultrasonography is the standard modality for screening and evaluation of the CNS, although because of its increasing availability, fetal MR imaging may soon supplant sonography as the standard. Ultrasonography remains widely available and is cost-effective. However, its accuracy depends on the experience of the ultrasonographer and is potentially limited by maternal obesity, oligohydramnios, and adjacent bony structures.¹³⁹ The

Fig. 15.18 Midsagittal T1-weighted magnetic resonance imaging of pontocerebellar hypoplasia. The vermis and cerebellar hemispheres are hypoplastic, and the ventral pons is flat.

limited view of standard ultrasound images can be overcome with three-dimensional sonography. Nevertheless, MR imaging adds a level of diagnostic accuracy notably better than that of ultrasonography¹⁴⁰

Fetal ultrasound can easily detect large anatomical defects specific to a malformation that otherwise would not be diagnosed until after birth. However, knowledge of the CNS embryology and its appearance on ultrasound at different gestational stages is important in avoiding incorrect diagnoses. For example, dysgenesis of the corpus callosum cannot be diagnosed until the 20th gestational week, when development of the commissure is normally complete. The cerebellar hemispheres and vermis continue to develop until after birth and can appear similar to cerebellar hypoplasia until the sixth or seventh month of gestation, when the posterior fossa cerebrospinal fluid space is replaced by brain.¹³⁹ On the other hand, obliteration of the cisterna magna, along with the lemon sign, banana sign, and possibly hydrocephalus, is consistent with Chiari malformation.¹⁴¹ Mildly enlarged ventricles are often normal in young fetuses, but the risk for developing hydrocephalus and having associated anomalies is significant when the ventricular width is greater than 15 mm.¹⁴² Extracerebral findings, such as facial dysmorphism and polyhydramnios, can also be indicators of CNS anomalies.¹⁴³

Subtle abnormalities, such as a smooth cortex in lissencephaly, can be difficult to detect by transabdominal ultrasound, even after 28 weeks of gestation, when the sulci and gyri are well defined. Difficult cases may be clarified by transvaginal neurosonography of the head in cephalic presentation, but these are ideally investigated with MR imaging of the fetus. Fast acquisition of images with the single-shot fast spin echo and half-Fourier acquisition single-shot turbo spin echo (HASTE) techniques minimizes artifacts caused by fetal movement.¹³⁹ It surpasses ultrasound in its anatomical resolution, size of the field of view, and ability to be reconstructed in multiple planes. The accuracy of MR imaging depends on the fetus's gestational age and is ideally delayed until the 20th week. More recent MR techniques add to the increasing armamentarium available for clinical diagnosis.¹⁴⁴

15.3 Surgical Treatment

The surgical treatment of congenital brain malformations is currently limited to the excision of mass lesions (LDD and congenital neoplasms) and dermal sinuses, repair of encephaloceles, shunting of cerebrospinal fluid for hydrocephalus, and epilepsy surgery. Of these, chronic epilepsy is the most difficult to manage, medically as well as surgically. The malformations associated with seizures are diverse, and the seizure semiology of each lesion type is mixed. In the largest study evaluating pediatric epilepsy with brain malformations, dysgenesis of the corpus callosum was the most frequent MR imaging finding, followed by equal numbers of cases of lissencephaly and focal cortical dysplasia, and finally pachygyria.¹⁴⁵ However, 80% of patients with dysgenesis of the corpus callosum and 55% of patients with lissencephaly had other brain anomalies. Other primary findings on MR imaging in epileptic children were polymicrogyria, heterotopia, schizencephaly, HPE, and hemimegalencephaly. In the study, the

seizures usually began early during infancy and often responded poorly to anticonvulsants.^{145,146}

Surgery for seizures is considered when all medical treatment options are exhausted. Preoperative MR imaging can reveal areas of abnormal gyri, thickened cortex, poor gray-white differentiation, and hyperintensity on T2-weighted images. Unfortunately, ideal candidates who have a surgically amenable unilateral lesion that correlates with preoperative fluorodeoxyglucose F 18 positron emission tomography (FDG-PET) and electroencephalography findings are infrequent. Seizure-free outcome after surgery for malformations of cortical development can be achieved in up to 50% of cases, but this success rate is low in comparison with those of surgery for hippocampal sclerosis.^{147,148} The lower success rate may be due to the coexistence of subtle dysplasias not detected by MR imaging and the presence of multiple epileptogenic zones that can be distant from, or even on the side opposite to, the visualized abnormality.¹⁴⁹ Patients with bilateral malformations and hemimegalencephaly have the least favorable outcomes, even after hemispherectomy for the latter.^{147,150,151}

Pearls

In these authors' experience:

- Most hemispheric malformations can be detected by fetal ultrasound, but subtle anomalies, especially those of the posterior fossa, require evaluation by in utero or postnatal MR imaging.
- In holoprosencephaly, the severity of facial dysmorphism may correlate with the degree of hemispheric noncleavage.
- Developmental delay is a common clinical presentation of hemispheric malformations but is also seen with cerebellar malformations.
- Seizures are usually associated with disorders of neuronal proliferation, differentiation, and migration and cortical organization. They often present early in life and become resistant to anticonvulsants.
- The child's neurologic prognosis depends upon the severity of the malformation and seizures.
- The surgeon's role in helping children with brain malformations attain their developmental potential is providing prompt surgery for hydrocephalus, tumors, and debilitating seizures.

16 Chiari Malformations

R. Shane Tubbs, Christoph Johannes Griessenauer, and W. Jerry Oakes

16.1 History and Classification

In the early 1890s, Dr. Hans Chiari¹ used autopsy specimens to describe four congenital anomalies, later termed the Chiari malformations (► Table 16.1). The four traditional varieties of Chiari malformation represent varying degrees of involvement of rhombencephalic derivatives. Three of these (types 1 through 3) have progressively more severe herniation of these structures outside the posterior fossa as their common feature. These three types also have in common a pathogenesis that involves a loss of the free movement of cerebrospinal fluid (CSF) out of the normal outlet channels of the fourth ventricle. Pathologic differences between Chiari 1 malformations (C1Ms) and Chiari 2 malformations (C2Ms) can be explained with knowledge of the differences in the timing of the development of the vector of force across the foramen magnum.

Although a large majority of cases are congenital, acquired C1Ms occur and are not rare. Not considered further in this chapter are the patients who have movement of their cerebellar tonsils into the cervical spine because of an intracranial tumor or other mass, especially within the posterior fossa. Technically, these patients have a C1 M, but treatment of the cause of their hindbrain hernia usually allows resolution of their secondary C1 M.

Several subclassifications have been developed for patients with hindbrain hernias, which are due to some problem with equilibrating CSF across the craniocervical junction. These classifications are as follows.

16.1.1 Chiari 0

Patients who do not appear to have significant hindbrain hernias, even though the posterior fossa may appear “crowded,” and who have large syringes that resolve with posterior fossa

decompression are classified as having Chiari 0 malformation.² Their condition indicates that they have a fourth ventricular outlet obstruction, and at surgery they frequently do have physical barriers to CSF movement but do not have caudal displacement of the cerebellar tonsils beyond a point that could be considered pathologic (<5 mm). These patients are included in the current chapter because their presentation and surgical intervention are the same as those of patients with frank hindbrain herniation.

16.1.2 Chiari 1

Patients in this common group have caudal displacement of the cerebellar tonsils more than 5 mm below the foramen magnum (► Fig. 16.1). The brainstem is in a normal position. They may or may not have a syrinx. The 5-mm “rule” concerning the definition of the pathologic extent of the caudal migration of the tonsils is arbitrary. Numerous patients have tonsils well below this point and are asymptomatic, especially young infants and children. When followed over time, they frequently remain asymptomatic if their initial evaluation was performed for an unrelated reason. The extent of their caudal migration may progressively decrease with time and become less impressive. This, however, is not certain, and the patient should be followed for the development of symptoms. A host of conditions are associated with the C1M. Many are listed in the box “Reported Associations with Chiari 1 Malformations (p. 193).”

Table 16.1 The classic Chiari malformations

Type	Characterized by:
Chiari type 1	Tonsillar herniation > 5 mm inferior to the McRae line No associated brainstem herniation or supratentorial anomalies Hydrocephalus uncommon Syringomyelia common
Chiari type 2	Herniation of the cerebellar vermis, brainstem, and fourth ventricle through the foramen magnum Almost always associated with myelomeningocele and multiple brain anomalies(see box “Findings Associated with Chiari 2 Malformations”)Hydrocephalus and syringomyelia very common
Chiari type 3	Foramen magnum encephalocele containing herniated cerebellar and brain stem tissue
Chiari type 4	Hypoplasia or aplasia of the cerebellum and tentorium cerebelli

Fig. 16.2 Sagittal magnetic resonance image illustrating tonsillar ectopia and caudal descent of the brainstem (i.e., the Chiari 1.5 malformation). Note the extensive syringomyelia with a skip region at C1–C2.

Reported Associations with Chiari 1 Malformations

- Klippel-Feil anomaly
- Odontoid retroflexion
- Growth hormone deficiency
- Neurofibromatosis
- Pierre Robin syndrome
- Costello syndrome
- Caudal regression syndrome
- Hemihypertrophy
- Lipomyelomeningocele
- Crouzon syndrome
- Apert syndrome
- Multisutural craniosynostosis
- Paget disease
- Craniometaphyseal dysplasia
- Rickets
- Acromegaly

16.1.3 Chiari 1.5

Although somewhat confusing, this term is applied to patients who bridge the gap between C1 M and C2 M. They have characteristics of both groups and are best considered separately. Their malformations are unassociated with neural tube defects, and caudal displacement of the cerebellar tonsils is similar to that in patients with C1 M. However, their brainstem and fourth ventricle are low, like those in patients with C2 M (► Fig. 16.2). In our series of patients without a neural tube defect and a hindbrain hernia, 17% had significant caudal displacement of the brainstem.³ Based on our series, these patients appear to have a greater chance of developing syringomyelia.

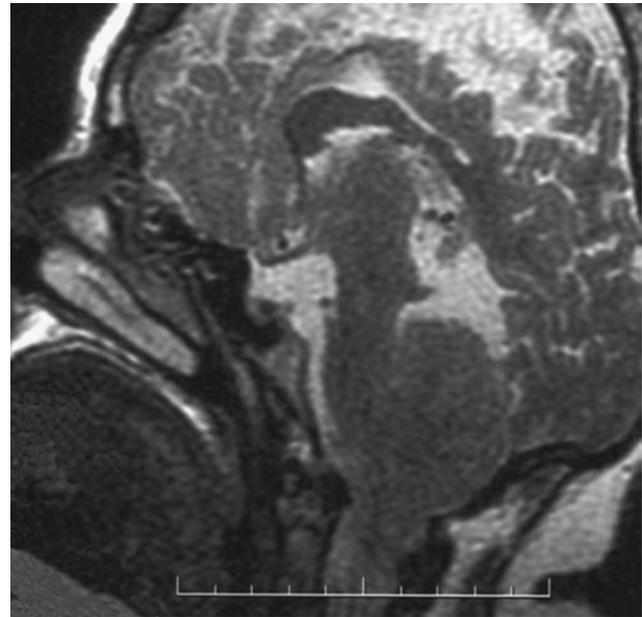

Fig. 16.3 Vermian herniation in the Chiari 2 malformation as demonstrated on a sagittal magnetic resonance image.

16.1.4 Chiari 2

This lesion occurs in patients with neural tube defects (myelomeningoceles and encephaloceles). It consists of caudal migration of the cerebellar vermis rather than of the cerebellar tonsils, brainstem, and fourth ventricle (► Fig. 16.3). Syringomyelia is common, as are a host of additional findings (see box “Findings Associated with Chiari 2 Malformations (p.193)”).

Findings Associated with Chiari 2 Malformations

- Skull
 - Craniolacunias
 - Scalloping of the petrous bones
 - Foreshortening of the internal acoustic meatus
 - Enlarged foramen magnum
 - Small posterior fossa
 - Notching of the opisthion
 - Scalloping of the frontal bone (lemon sign)
 - Cranioschisis
 - Clival concavity
 - Inferiorly displaced inion
 - Midline occipital keel
 - Assimilation of the atlas
- Spine
 - Enlarged cervical canal
 - Scalloping of the odontoid process
 - Incomplete posterior arch of C1
 - Klippel-Feil deformity
 - Basilar invagination

- Ventricle/cistern
 - Hydrocephalus
 - Asymmetry of the lateral ventricles
 - Lateral pointing of the frontal horns
 - Colpocephaly
 - Shark tooth deformity of the third ventricle
 - Commissure of Meynert
 - Small fourth ventricle that is flat and elongated
 - Extraventricular location of the choroid plexus of the fourth ventricle
 - Absence of the inferior medullary velum
 - Absence or cyst of the foramen of Magendie
 - Enlarged cerebellar and pontine cisterns
- Meninges
 - Widened, heart-shaped, low-lying, hypoplastic, venous lake-engorged tentorium cerebelli
 - Vertical straight sinus
 - Confluence of sinuses near opisthion
 - Falx cerebri/cerebelli hypoplasia/aplasia
 - Thickening of the leptomeninges at the foramen magnum
 - Arachnoid cysts of the cervical canal
 - Thickening of the cephalic dentate ligaments
- Spinal cord
 - Split-cord malformation
 - Syringomyelia
 - Exophytic syringes
 - Shortened and caudally displaced cervical spinal cord
 - Reduced neuronal counts in the cervical cord
 - Reduction in myelination of the corticospinal tracts
- Telencephalon
 - Complete or partial agenesis of the corpus callosum and/or septum pellucidum
 - Polygyria
 - Chinese lettering (interdigitation of the parieto-occipital lobes)
 - Agenesis of the olfactory tract and bulb
 - Agenesis of the cingulate gyrus
 - Prominence of the head of the caudate nucleus
 - Heterotopias
- Diencephalon
 - Enlarged massa intermedia
 - Anterior displacement of the massa intermedia
 - Elevation of the hypothalamus
 - Elongation of the habenular commissure and pineal gland
- Mesencephalon
 - Elongation of the midbrain with a shortened tectum
 - Tectal beaking (fusion of the superior and inferior colliculi)
 - Stenotic, stretched, forked, or kinked cerebral aqueduct
- Metencephalon
 - Small cerebellum that may tower superior to the tentorium cerebelli
 - Vermian herniation through the foramen magnum
 - Cranial nerves that traverse the cerebellar folia and that may be dysplastic
 - Curvature (inversion) of the cerebellum with resultant “kissing” of the left and right sides (banana sign) anterior to the brainstem
 - Cerebellar heterotopias
 - Dysplastic deep gray matter

- Elongation of the pons with indentation of its ventral surface
- Caudal displacement of the basivertebral arteries
- Dysplastic pontine basal nuclei
- Dysplastic tegmental and cranial nerve nuclei of the pons
- Myelencephalon
 - Elongation and flattening of the medulla producing a “trumpet-like” structure
 - Protuberance (medullary kink, hump, spur, buckle) caudal to the gracile and cuneate tubercles
 - Cephalically located pyramidal decussation

16.1.5 Chiari 3

The Chiari 3 malformation is a rare and extreme form of hindbrain hernia. It is found in fewer than 1% of all patients in this category. Patients have a high cervical sac containing significant portions of the cerebellum and/or brainstem. There are frequently other associated anomalies, similar to those in patients with C2 M (► Fig. 16.4). Hydrocephalus is common, and severe neurologic and developmental problems are usually present. Treatment consists of ensuring that skin covers the lesions and that tethering is not an issue. This malformation will not be considered further because of its rarity and the limited role that neurosurgery plays in its care.

16.1.6 Chiari 4

Patients with type 4 Chiari malformation have cerebellar hypoplasia or aplasia. This is not a form of hindbrain hernia. Therefore, inclusion in a discussion of hindbrain hernias is questionable, and this malformation will not be considered further.

16.2 Signs and Symptoms

16.2.1 Chiari 1 Malformations

Patients with a C1 M may present with a variety of symptoms and signs ranging from headache to severe myelopathy and brainstem compromise (see box “Clinical Presentation of a Chiari 1 Malformation (p.195)”). The most common presenting symptom is pain (60 to 70%),⁴ usually occipital or upper cervical in location and often induced or exacerbated by Valsalva maneuvers such as coughing, laughing, and sneezing. In infants and children who are unable to communicate verbally, headaches may be manifested simply by irritability or grabbing at the neck.⁵ As many as half of the patients with a Valsalva-induced headache will be found to have a C1 M as the cause. If the headache is not Valsalva-induced and if the pain is farther away from the craniocervical junction, it is less likely that a hindbrain hernia is the cause. Adolescents who have a symptom complex with vague frontal or vertex headaches, no syrinx, a normal neurologic examination, and a descent of the tonsils of 5 mm or more is very unlikely to improve symptomatically if a Chiari decompression is performed. This should be contrasted with the 6-month-old child who cries and then reaches for the posterior cervical region, grimaces, and arches the spine. In this case, the original neck pain is relieved postoperatively.

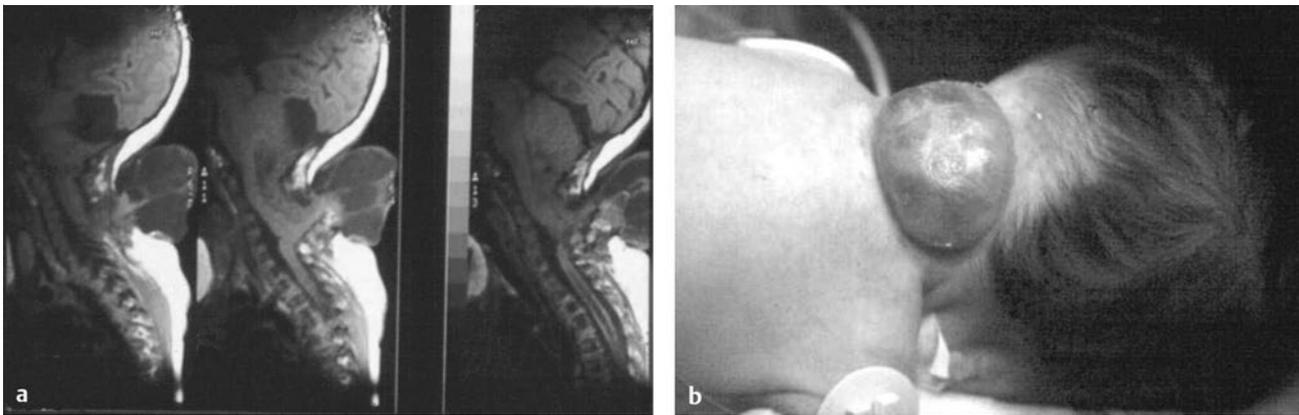

Fig. 16.4 (a) Sagittal magnetic resonance images and clinical image of a type 3 Chiari malformation, (b) with hindbrain herniation through an upper cervical spina bifida.

Clinical Presentation of a Chiari 1 Malformation

- Symptoms
 - Occipitocervical headaches/dysesthesia
 - Nonradicular pain in the back, shoulders, and limbs
 - Motor and sensory symptoms
 - Clumsiness
 - Dysphagia
 - Dysarthria
- Cerebellar syndrome
 - Truncal and appendicular ataxia
- Brainstem syndrome
 - Respiratory irregularities
 - Nystagmus
 - Lower cranial nerve dysfunction, including otologic disturbances
 - Recurrent aspiration
 - Hypertension (rare)
 - Glossal atrophy
 - Facial sensory loss
 - Trigeminal or glossopharyngeal neuralgia
- Spinal cord syndrome
 - Motor and sensory losses, especially in the hands
 - Hyporeflexia
 - Hyperreflexia
 - Babinski response
- Other signs
 - Oscillopsia
 - Esotropia
 - Sinus bradycardia
 - Progressive scoliosis
 - Hoarseness
 - Hiccups
 - Urinary incontinence
 - Drop attacks
 - Scoliosis

Another major symptom complex includes scoliosis. Scoliosis associated with syringomyelia may sometimes be differentiated from idiopathic scoliosis by a left thoracic curve, abnormal abdominal reflexes, or diffuse nondermatomal pain in the flank or back. Any neurologic abnormality, uncharacteristic pain, or other worrisome change in a patient with scoliosis should alert the clinician to the possibility of a syrinx caused by a C1 M.

Other unique symptom complexes may be grouped according to the anatomical area affected: brainstem and cranial nerves, spinal cord, and cerebellum.

Symptom complexes that localize to the brainstem include tongue atrophy, downbeat nystagmus (indicative of medullary dysfunction), and extraocular muscle changes (even an isolated sixth nerve palsy or paresis). Lower cranial nerve dysfunction may occur in 15 to 25% of patients, with gagging, sleep apnea, and difficulty swallowing.⁶⁻⁸ Oropharyngeal dysfunction is common and can manifest as poor feeding, failure to thrive, recurrent aspiration pneumonia, and dysphagia.⁹ Vocal cord paralysis with stridor or hoarseness is rarely present and is similar to the symptoms of patients with C2 M.

Spinal cord dysfunction is the result of direct cord compression or a syrinx (► Fig. 16.5, ► Fig. 16.6, and ► Fig. 16.7). Older adolescents may describe the classic suspended, dissociated sensory loss, but this will rarely be a spontaneous complaint. The loss of pain and temperature sensation with preservation of light touch and proprioception, when present, will appear over the trunk or hands. This occurs as the crossing fibers are damaged by the progressive enlargement of the intramedullary process. The mechanism of causation of scoliosis is not fully understood. It can be argued that the asymmetric weakness of the paravertebral musculature causes a postural imbalance that manifests as scoliosis.

Interestingly, cerebellar dysfunction as a presentation is rare. Cerebellar signs, other than nystagmus, are also rare. There is no apparent neurologic localization for the cerebellar tonsils, despite the presence of gliosis and ischemia commonly seen at operation.

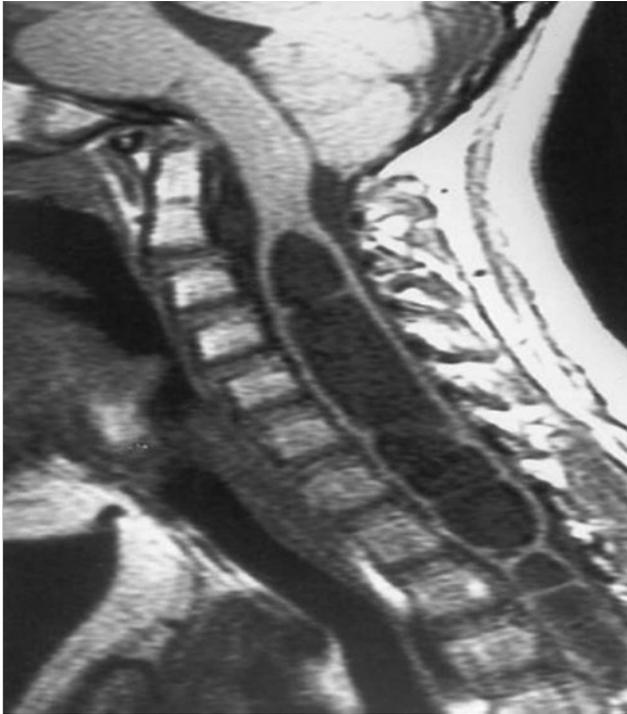

Fig. 16.5 Sagittal magnetic resonance image of a patient with Chiari 1 malformation and a huge syringomyelia. Note the septa (haustri) within the syrinx.

Fig. 16.6 T2-weighted sagittal magnetic resonance image of a patient with Chiari 1 malformation. Note the tonsillar level of C2 and the small cervical syrinx.

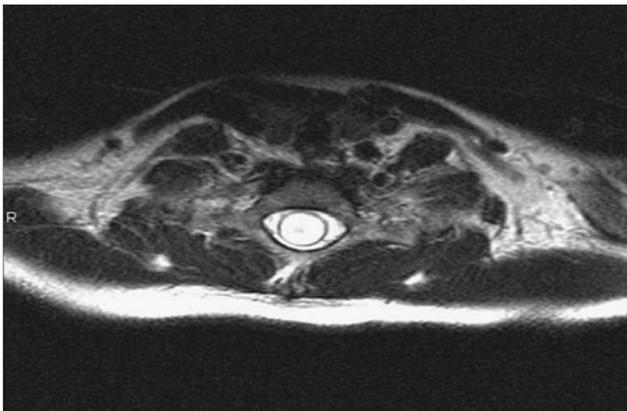

Fig. 16.7 Axial magnetic resonance image through the cervical portion of a holocord syrinx in a young girl. Note the extremely thin nature of the spinal cord. This patient surprisingly had very little symptomatology and presented with scoliosis.

16.2.2 Chiari 2 Malformations

Symptoms of C2M occur characteristically within age groups. As many as one-third of neonates and infants with myelomeningocele may present with serious life-threatening apnea,

inspiratory stridor, dysphagia, and bradycardia. The apnea is frequently associated with breath-holding spells. The dysphagia may be so severe that there is a failure to thrive. When these symptoms are present at birth, the situation is grave and implies hypoplasia or aplasia of the appropriate medullary nuclei. If present at birth, the symptoms are generally not reversible. It is more common that medullary symptoms begin within the first few months of life. They may be associated with opisthotonos. When these symptoms develop, normalization of the intracranial pressure with shunt insertion or revision is necessary for active support of the infant.

With regard to the inspiratory wheezing so characteristic of this situation, the “crowing” sound tends to fluctuate with time, increasing with anxiety and diminishing with sleep. When the sound is present while the patient is at rest, the situation is critical and warrants urgent attention.

Older children most commonly display symptoms and signs of spinal cord compromise, with lower motor neuron problems in the arms and upper motor signs and symptoms in the legs. Hyperreflexia in the legs of a patient with myelomeningocele generally requires investigation.

As in patients with C1 M, cerebellar signs (other than nystagmus) are uncommon and very rarely a reason for clinical presentation. The box “Clinical Presentation of the Chiari 2 Malformation (p. 197)” summarizes the clinical presentation of patients with C2 M.

Clinical Presentation of the Chiari 2 Malformation

- Newborns
 - Usually asymptomatic
- Infants
 - Signs of brainstem compression
 - Stridor secondary to vocal cord paralysis
 - Central and obstructive apnea
 - Aspiration secondary to dysphagia with potential pneumonia
 - Failure to thrive secondary to dysphagia
 - Breath-holding spells with possible loss of consciousness
 - Hypotonia and quadriparesis
 - Irritability
 - Opisthotonos
- Older children and young adults
 - Spinal, cerebellar, and ophthalmologic signs
 - Occipitocervical pain
 - Hand weakness and loss of muscle bulk
 - Myelopathy
 - Ataxia
 - Strabismus
 - Nystagmus
 - Defects of pursuit movements and convergence
 - Defects of optokinetic movements
 - Scoliosis
 - Dysarthria
- Neurologic emergency
 - Usually younger than 2 years, commonly by 3 months of age
 - Progressive neck pain
 - Apnea
 - Dysphagia
 - Stridor
 - Opisthotonos
 - Nystagmus
 - Progressive brainstem dysfunction

16.3 Diagnostic Studies

16.3.1 Computed Tomography and Magnetic Resonance Imaging

Chiari 1 Malformations

C1 M consists of significant herniation of the cerebellar tonsils through the foramen magnum. Reasonable criteria for this diagnosis include herniation of one or both tonsils at least 5 mm below the foramen magnum accompanied by other C1 M features, such as syringomyelia.¹⁰ The tonsillar tip may be pointed, carrying further pathologic significance, or be blunt and rounded, causing less concern. The foramen magnum will appear crowded, with a lack of CSF surrounding the tonsils on T2-weighted magnetic resonance (MR) imaging. In addition, accurate diagnostic guidelines should include the absence of an intracranial mass lesion or hydrocephalus. The liberal use of MR imaging over the last 20 years has greatly facilitated the diagnosis of C1 M and increased its apparent incidence. The true incidence of C1 M is not known. However, in 7,400 brain

dissections, Friede¹¹ found 2 cases plus 46 additional examples of “chronic tonsillar herniation,” which may include many patients who are now classified as having a C1 M.

In an early review of 800 MR imaging examinations, one study¹² noted that “normal” or “asymptomatic” patients might have tonsils that extend 3 mm below the foramen magnum. The tonsillar herniation was much more likely to be pathologic when it exceeded 5 mm. Similarly, Barkovich et al¹³ studied 200 normal patients and 25 patients with a “firm” diagnosis of C1 M. A distance of 2 mm below the foramen magnum was considered the lowest extent of the tonsils in normal patients (specificity of 98.5%, including three false-positive results, and sensitivity of 100%). A distance of 3 mm below the foramen magnum was considered the lowest extent in normal patients (sensitivity of 96% and specificity of 99.5%). An additional study has documented ascent of the tonsils with increasing age.¹⁴

From these studies, it is clear that the practicing pediatric neurosurgeon will see frequent exceptions to the measurements listed above. These studies are useful in screening patients, but the symptom complexes must be analyzed together with the radiologic findings. Patients imaged early in life for unrelated reasons and asymptomatic for Chiari symptomatology may have very impressive MR images. Observing numerous patients in this category who are without symptoms or a syrinx has led us to advocate a conservative approach to intervention. However, operative intervention should be considered for patients with a large syrinx and unimpressive hindbrain herniation and no other cause for the syrinx.

Other associated radiologic anomalies occur infrequently; they most commonly include atlanto-occipital assimilation, basilar invagination, and fused cervical vertebrae. These findings are important to know before surgical positioning.

The combination of hydrocephalus and a C1 M is a special subject and is covered later in this chapter. It must be excluded before a family is advised on a course of action.

Chiari 2 Malformations

Patients with a C2 M are characterized by (1) elongation and caudal displacement of the cerebellar vermis and brainstem structures, (2) the presence of a myelomeningocele or encephalocele in virtually all cases, and (3) hydrocephalus in the majority of cases. Syringomyelia is also commonly seen in this situation (40 to 95%), especially in the lower cervical cord. Other anomalies associated with C2 M (see box “Findings Associated with Chiari 2 Malformations (p. 193)”) comprise a set of cranial and spinal malformations. None of these findings is in itself pathognomonic for a hindbrain hernia, but their coexistence is suggestive of a C2 M (► Fig. 16.8 and ► Fig. 16.9). Studies that might be performed in addition to computed tomography (CT) and MR imaging include sleep studies to evaluate for sleep apnea, swallowing studies to demonstrate cricopharyngeal achalasia, and laryngoscopy to verify movement of the vocal cords.

16.3.2 Pathology and Pathobiology

Although the different types of Chiari anomalies involve many of the same anatomical structures, their pathoembryologic origins appear to be distinct. In this section, we attempt a historical overview of the main theories of the first two types of Chiari

Fig. 16.8 Magnetic resonance image of a Chiari 2 malformation. Note the dysplasia of the corpus callosum, large massa intermedia, flattened pons and medulla, vermian herniation and upward herniation of the cerebellum, tectal beaking, and caudal descent of the confluence of the sinuses.

malformations in an effort to understand the anatomy of these lesions and some of the logic behind the different therapeutic strategies. It is important to note that any acceptable theory of the pathogenesis of Chiari malformations should be able to explain the associated brain and spinal cord malformations.

In his initial description, Chiari¹ suggested that hindbrain hernias resulted from hydrocephalus, and that the different Chiari malformations consisted of degrees of expression of that same mechanism. Since then, several other theories have been presented; these distinguished between the embryology of the different malformations and debated whether some of the lesions were purely dysraphic or the result of the interplay of intracranial and intraspinal mechanical forces. Chiari's description of acquired Chiari malformations, together with the demonstration of dynamic shifts on cine-mode MR imaging, suggests that Chiari malformations are not merely fixed dysraphic lesions. Instead, they may be dynamic entities that can change with time.

The theories of the pathogenesis of Chiari malformations include the hindbrain dysgenesis and developmental arrest theory, the caudal traction theory, the hydrocephalic and hydrodynamic theory of Gardner, the small posterior fossa/hindbrain overgrowth theory, and the lack of embryologic ventricular distention theory.¹⁵

Chiari believed that the first three types of malformation resulted directly from chronic hydrocephalus. In his 1891 article,¹ he stated that he had never seen a hindbrain hernia that was not associated with hydrocephalus; he added that chronic hydrocephalus could possibly cause the cerebellum to develop abnormally and to herniate into the foramen magnum. The occurrence of Chiari malformations without hydrocephalus and the coexistence of other anomalies, such as myelomeningoceles and split-cord malformations, was much more involved. In addition, one of the most significant components of C2Ms is the

upward herniation of posterior fossa structures through the tentorial notch into the supratentorial compartment. This too would not be consistent with such a theory.

One of the earliest views of pathogenesis stated that tethering of the spinal cord might cause the posterior fossa structures to be pulled down into the spinal canal. Aside from the fact that this theory could not explain the cervicomedullary kink and other Chiari 2 anomalies, experimental evidence in animals has disproved the theory altogether.

In his original description of a hindbrain hernia in an autopsy specimen with a myelomeningocele, Cleland was the first to support the dysraphic theory.³⁵ Recent pathologic studies have demonstrated aplastic or dysplastic changes in the brainstem specifically affecting the cranial nerve nuclei, cerebellum, thalamus, and corpus callosum, further supporting a dysgenesis theory. Nonetheless, this theory has been found to be inadequate because it still does not explain the other cranial malformations found in these patients and is not compatible with the dynamic shifts outlined above.

In the 1950s and early 1960s, Gardner¹⁶ presented his hydrodynamic theory, which stated that in normal embryology, CSF pulsations from the choroid plexus (previously described by Bering)¹⁷ play a significant role in the expansion of the neural tube).¹⁷ was later significantly expanded by Williams.¹⁸ According to Gardner, these pulsations help in the development of the arachnoid pathways, as well as in the modeling of the expanding brain. He believed that the balance between the pulsatile flow in the supratentorial and fourth ventricular choroid plexus directed brain growth differentially. Therefore, if the fourth ventricular pulsations are overactive, the tentorium is pushed upward and a Dandy-Walker malformation can develop. Conversely, if the supratentorial pulsations are overactive, tentorial migration becomes such that the posterior fossa is small,

allowing the development of a Chiari anomaly as outlined below; in addition, the CSF outlets of the fourth ventricle remain closed, directing the CSF into the patent opening at the obex, thus causing syringohydromyelia.¹⁷

Based on experimental manometric evidence in normal persons and in patients with Chiari malformation, Williams¹⁸ expanded on Gardner's theory by suggesting that Valsalva maneuvers result in epidural venous congestion and intracranial as well as intraspinal rises in pressure, causing fluid to flow both cranially and caudally. Although flow into the cranial compartment meets no resistance, caudal flow is delayed by hindbrain adhesions and outlet obstruction, thus creating a pressure differential between the cranial and spinal compartments. This pressure differential may last a few seconds and cause worsening hindbrain impaction and syringohydromyelia. Heiss et al have shown with intraoperative ultrasound that during systole, the associated syrinx decreases in size, and during diastole, the syrinx grows in size.³⁶ Repeated measurements made after surgical decompression showed equilibration of the pressures in the two compartments; this in turn, correlated with clinical improvement.¹⁸ However, spinal cord cavitation is often acquired (as in posttraumatic syringohydromyelia), and a connection between the cyst and the fourth ventricle is not always present, which raises doubts about the adequacy of this theory. In addition, acquired C1Ms have been extensively reported after multiple lumbar punctures,¹⁹ lumbar-peritoneal shunting,²⁰ and spinal arachnoid shunting,²¹ and also arising spontaneously without external intervention.²² A case report describing a fatal case of chronic tonsillar herniation after a lumbar puncture and lumbar-peritoneal shunt revision in a patient with Crouzon disease is a dramatic example of this point.²⁰ Explanations of the pathophysiology of acquired tonsillar herniation have been mainly based on the pressure differential created by lumbar CSF diversion. One hypothesis states that the siphoning of CSF causes a pressure gradient that directly induces the cerebellum to descend. Another hypothesis attributes the herniation to skull growth arrest secondary to chronic CSF siphoning. In these cases, the growing brain is limited by a small posterior fossa volume.²³ However, these hypotheses do not explain the cases of spontaneous herniation. Amin-Hanjani et al²³ have attempted to explain this phenomenon by hypothesizing that a mismatch in the growth of the bony and neural components of the posterior fossa occurs during development. Because the cerebellum reaches approximately 80% of its adult weight in the first year of life, a small posterior fossa may be limiting enough to induce this rapidly expanding neural structure to herniate. Marin-Padilla and Marin-Padilla²⁴ initially described the small posterior fossa theory in 1981. The treatment of hamster embryos with vitamin A induced mesodermal insufficiency in these animals, leading to underdevelopment of the occipital bone and a small posterior fossa. It was hypothesized that a small posterior fossa would act as a barrier against continued growth of the posterior fossa neural structures, thus pushing these structures downward and upward outside the confines of the fossa. Rachitic patients with bony overgrowth of the posterior fossa (► Fig. 16.10) have a high incidence of C1M. Patients with growth hormone deficiency may have an incidence of C1M as high as 20%.²⁵ Both these groups support a theory that restricted posterior fossa volume will be associated with the development of hindbrain hernias. Lastly, the increased incidence

Fig. 16.10 Operative demonstration of massive cerebellar herniation (elevated with the forceps) over the cervical spinal cord (C4).

of C1M in patients with craniosynostosis lends credence to a small or restricted skull resulting in tonsillar ectopia. C1M is especially observed in patients with synostosis of the lambdoid suture(s).

How can a single theory of pathogenesis explain all the anatomical abnormalities associated with Chiari malformations? Do the different types of hindbrain herniation belong to the same spectrum of malformations and differ only in degree, or are they truly distinct entities with different embryologic etiologies? Osaka et al,²⁶ who found that the neural tube defect occurred before the hindbrain deformity in affected fetuses and embryos, have evaluated the association of Chiari malformations with myelomeningocele. Because the cerebellar vermis develops before the tonsils, an abnormal pressure differential developing in utero would cause abnormal displacement of the vermis and brainstem structures, without any tonsillar involvement. Such a pressure differential could occur with fluid leakage from the myelomeningocele.

McLone and Knepper¹⁵ have advanced a “unified theory” that would explain the cause of the C2M along with most, if not all, of the associated anomalies. This theory is based on the above assumption that the neural tube defect occurs first; all the other manifestations, including the Chiari malformation and hydrocephalus, follow secondarily. Leakage of CSF through the spinal defect causes a lack of distention of the primitive cranial ventricular system. Multiple abnormalities form because mechanical support from normally distended primitive ventricles is a prerequisite for the normal development of the cerebral cortex and overlying skull. In experimental animals, venting fluid from the embryonic ventricular system causes disorganization of the developing cerebral cortex. In addition, the tentorium is left low, which leads to a small posterior fossa, abnormal development of the pontine flexure, and herniation of posterior fossa structures downward through the foramen magnum and upward through the tentorial notch. The lack of distention of

the third ventricle was hypothesized to cause the thalami to remain in apposition, resulting in a large massa intermedia. Even lückenschädel was thought to form because of a lack of distention of the underlying neural mass, a requisite for collagen organization and normal ossification.

In summary, the current best evidence is that the development of a craniospinal pressure gradient across the foramen magnum will cause or hasten the development of a hindbrain hernia. If this occurs after the development of the cerebellar tonsils, they will move through the foramen magnum. If the gradient occurs before the development of the tonsils, in utero, the vermis will be caudally displaced. The gradient results from impaired CSF flow across the foramen magnum. CSF enters the intracranial compartment from the intraspinal compartment easily, but its egress is impeded. There is a vector of force out of the intracranial compartment. This mechanism is responsible for most cases of acquired C1 M, although congenital factors can create this situation, as well. Conversely, intracranial pathology such as mass lesions and hydrocephalus may increase the gradient of intracranial pressure to spinal pressure, causing C1 M. Lumbar–peritoneal shunting, repetitive lumbar punctures, lumbar drainage, and chronic spinal CSF leaks of an iatrogenic nature are all causes of an acquired C1 M.

16.4 Treatment

16.4.1 Chiari 1 Malformations

Surgical Indications

No effective nonsurgical alternative exists for symptomatic patients with C1 M. The benefit of surgery in changing the clinical course of patients with C1 M has been documented in retrospective studies from the past several decades. The immediate relief of symptoms and the objective decrease in the size of syringes following surgical intervention have substituted for precise knowledge of the natural history. The discussion then is not as much about whether patients with hindbrain hernias should be surgically treated, but rather about (1) whether the definition of significant hindbrain herniation should be tightened, (2) the timing of surgery, and (3) the specifics of the operation.

Some basic principles are generally agreed upon. If hydrocephalus coexists or any question of raised intracranial pressure is present, this situation should be resolved before any consideration is given to decompression. The likelihood of a craniocervical decompression resolving appropriate symptoms is 80 to 85%, with minimal operative risk.³ Syringes generally show evidence of decreasing in size or totally resolving within 6 months of surgery. A lack of resolution of symptoms, especially headache, generally indicates improper patient selection. Not all patients with 5 mm of caudal descent of the tonsils and headache will improve with Chiari decompression. The more typical the headache with Valsalva induction, especially if the patient can reproduce the headache consistently with a single maneuver, the greater the likelihood the problem will be resolved. The less typical the pain, especially without a Valsalva-induced component, the less likely surgery will be effective. Between these two extremes, clinical judgment will help guide decision making. We have no experience with repeated decompression for headache if the initial decompression is unsuccessful. When an asso-

ciated syrinx is present and symptomatic, more objective criteria are to be followed. In more than 90% of patients, the syrinx will respond within 6 months both clinically and radiologically. With time, in at least 5 to 10%, a syrinx and symptoms will redevelop. This group, together with the small group that does not respond initially, has a high (>90%) likelihood of responding to a secondary decompression in which resection of one or both tonsils is performed.³ With this in mind, some surgeons have incorporated tonsillar resection with the initial procedure. We have not, reserving the resection of brain for a secondary procedure. Such internal decompression of the tonsils consists of resection to a point of visualization of the inferior aspect of the fourth ventricle without retraction. Alternative steps are simply to coagulate the tonsil and cause it to shrink. If this method is chosen, the surgeon should attempt to minimize trauma/injury to the medial surface of the tonsil as scarring there may be associated with recurrent symptoms. During a secondary decompression, the surgeon must weigh additional bony decompression and dural opening and grafting, resulting in a wider decompression, against the possibility of the development of cerebellar ptosis, or “slump,” which is a serious complication. We have not experienced this problem, undoubtedly because our opening is usually “adequate,” but not excessive. This opening is 22 to 25 mm in width at the foramen magnum and about the same distance in height. Having said that, with recurrent or inadequate clinical outcome, thought should be given to expanding the internal decompression. This maneuver during a second procedure has been helpful in postoperative patients referred to us, as well as in our own initial failures. The internal decompression consists of tonsillar resection to the point of visualization of the inferior aspect of the fourth ventricle without retraction.

An error that we have committed has been in choosing dorsal decompression when some ventral compression coexisted. In defining what is “significant” ventral compression, we propose that when the ventral compression exceeds 9 mm (perpendicular distance from a plane drawn between the basion and the posterior–inferior aspect of C2), a risk in dorsal decompression exists (► Fig. 16.11).²⁷ When more than 9 mm of ventral

compression exists but the patient does not have significant medullary symptomatology, a judgment should be made as to the risk for deterioration from dorsal decompression versus the risk for transoral decompression and occipitocervical fusion. When ventral compression is severe, this decision is simple, and transoral decompression is necessary. Spinal instability at the craniocervical junction is rarely present. This should be investigated with flexion–extension X-rays before surgery if any question exists.

In the setting of hindbrain herniation and syrinx, we have not placed a syringopleural or peritoneal shunt in the past two decades. Shunting the syrinx with the necessary myelotomy will result in some sensory loss with possibly additional neurologic difficulties. These shunts will malfunction with a concerning frequency in selected patients, and revision of the system frequently requires replacement of the syrinx catheter or its adjustment. This maneuver has always been of concern because of the risk for significant spinal cord injury.

Patient Selection

Appropriate selection of the patients likely to respond to surgical therapy can be challenging. Surgical indications vary among physicians, especially for subjective symptoms such as headache. A 1998 opinion survey of North American pediatric neurosurgeons concluded that there was widespread agreement to treat patients with a syrinx and progressive scoliosis or symptoms.²⁸ Opinions were mixed on how to manage individuals with asymptomatic syringes. Opinions varied widely on the most appropriate surgical technique. With a lack of objective data comparing various surgical techniques, we will simply outline our approach and record the results.

Acquiring adequate imaging and clinical data is the first step in managing this diverse group of patients. Patients suspected of having C1 M should undergo MR imaging of the brain and entire spine to assess tonsillar ectopia, rule out hydrocephalus, and screen for a syrinx. Cine MR imaging may be used to assess CSF flow at the foramen magnum, but it has been of little use to us in determining indications for operation. This is not to say that we do not believe in the concept of looking, but simply that the currently available software has not proved to be useful in making clinical decisions. The size of the ventricles is assessed as previously outlined, and flexion–extension radiographs of the cervical spine are obtained in the unlikely event that there is instability.

Generally, tonsillar herniation greater than 5 mm is considered abnormal, but not necessarily indicative of the need for treatment. Individuals with less hindbrain herniation and large symptomatic syringes may have functional limitation of the egress of CSF from the fourth ventricle. They may very well benefit from decompression. A large hindbrain hernia may remain asymptomatic for years and in infancy and childhood may progressively become less impressive with time. Hence, the diagnosis and recommendation for surgery for patients with C1 M must be based on both clinical and radiologic criteria.

Once patients are determined to have idiopathic C1 M and hydrocephalus is ruled out, they are divided into two broad categories based on the presence or absence of a syrinx. In our

clinic, the vast majority of patients with a syrinx and significant hindbrain hernia are offered surgical decompression. The more significant the symptoms, the easier it is to justify this position. Patients with a visible central canal and minimal herniation are followed. This strategy is based on the belief that a syrinx is indicative of pathologic forces acting on the spinal cord that should be corrected to prevent permanent cord damage. This approach is not universal; some authors advocate a conservative approach for small asymptomatic syringes.²⁹

In patients without syringes, the situation is much more subjective. A patient with Valsalva-induced occipital headache/neck pain that is easily reproducible, of short duration (seconds to minutes), and life-dominating is at the easiest end of the spectrum for rendering a judgment. Without a clear element of Valsalva induction of the pain, even with impressive degrees of hindbrain herniation, the patient may not benefit from surgery. We do not offer decompression for headache alone without a clear abnormality on MR imaging (caudal descent of the tonsils of > 5 mm and appropriate characteristics of the headache). The most difficult situation we deal with is the child with 5 mm of caudal descent, no syrinx, and severe, life-dominating, diffuse headache unresponsive to medical intervention. In this situation, the family and referring neurologist may repeatedly point to the X-ray report outlining the diagnosis of C1 M. An in-depth discussion with the family regarding the lower likelihood of success in alleviating the headache with surgery may help. Involvement of a medical specialist in headache is frequently of help.

The third group comprises patients who have a wide variety of symptoms and signs. They require more discussion. Symptom complexes may be unique and not appear in standard symptom lists. The infant who is a poor feeder or who has downbeat nystagmus, nasal speech, malignant hiccups, and even rarely essential hypertension may have a hindbrain hernia as the etiology. The challenge with this group is to be able to localize the symptoms to the brainstem and think to perform MR imaging. Patients with medullary dysfunction related to breathing and swallowing should not be given a trial of conservative care before surgical decompression. This may be a more important message for the nonsurgical community.

Surgical Technique

With knowledge that the intracranial pressure is normal and the cervical spine stable, the patient is positioned prone with the neck flexed. This position is held with a pin fixation device. We use pin fixation devices even in young children and infants. The clamp is tightened until tension appears in the anterior fontanel. Care is taken to position the pins in front of the equator of the skull on the dependent half of the skull, forcing the skull into the fixation device. The body is held on the table with tape in small children or with a footboard in older children, and the head is raised until the operative field is parallel to the ground. The incision extends from the C2 spinous process to a point just below the external occipital protuberance. The midline of the posterior cervical musculature is identified by the small amount of fat within it and the muscles separated. Care is taken not to disrupt the muscle insertion superiorly or

inferiorly at C2. Lateral exposure is the width of the spinal canal at C1 and approximately 50% more than that in the occipital region. A suboccipital craniectomy and removal of the posterior arch of C1 are performed, with a realization that the pathology is in the midline. The dorsal dura at C1 is exposed and the foramen magnum until the bone becomes more vertical to the operator. The dura is opened in a linear fashion beginning in the cervical region. Traction stitches are applied to the full thickness of the dura to help control bleeding from the occipital sinus. If necessary, horizontal incisions are made in the dura at the level of maximum constriction (usually the foramen magnum) to allow additional relaxation. The arachnoid is opened off the midline and clipped to the dura with metal clips, in effect fusing the two layers. The fourth ventricle is explored by separating the cerebellar tonsils. Adhesions that prevent separation of the tonsils are lysed. The avascular floor of the fourth ventricle is appreciated. A pericranial graft is harvested through a separate incision that is large enough to provide a tension-free dural patch.

There are many variations of this technique, with numerous authors advocating bony decompression alone or dural opening without arachnoidal disruption. Each of these approaches has its champions. Our purpose here, without any randomized trial data, is to describe how this procedure has evolved in our practice. The justifications for each step are generally a complication of our own or of one of our colleagues that we are trying to avoid.

16.4.2 Chiari 2 Malformations

Surgical Indications and Technique

The natural history of patients with a C2 M seems to be age-dependent. In the series of Pollack et al³⁰ of 25 patients with symptomatic C2 M, 13 neonates presented with symptoms of brainstem dysfunction before 3 months of age and 12 patients presented after this period. In the older group, no patient died or had a poor outcome. Of the neonates, 23% died, 16% had a poor outcome, and the remainder had a good outcome. In the prospective series of Pollack et al,³¹ approximately 77% of symptomatic patients recovered normal or nearly normal brainstem function following decompression (occipital craniectomy and laminectomy). A presentation with bilateral vocal cord paralysis was found to have the worst prognosis. The results of Pollack et al are contrasted with the experience of Bell et al,³² whose success rate was only 30%. In our own experience, the results are directly related to how carefully one looks for symptoms and signs. At least one-third of patients with a closed myelomeningocele and shunted hydrocephalus will develop medullary dysfunction. This becomes progressively less likely the older the patient becomes. Before 3 months of age, symptoms may very well be life-threatening.

What has become increasingly clear to us is the relationship of symptoms of medullary dysfunction to shunt function. The adage "It's a shunt malfunction until proven otherwise" is correct in the vast majority of patients, and the number of C2 M decompressions we perform has drastically decreased since this realization. The criteria we use to determine shunt

malfunction is as follows. The patient with myelomeningocele who presents with medullary dysfunction and a brain image that may very well be improved from the preshunt image is still considered to have shunt malfunction as the reversible cause of the symptoms. Even patients with normal or small ventricles are brought to the operating room for surgical inspection of the shunt when medullary symptoms are present. In addition, the infant or myelodysplastic child who experiences neck pain is assumed to have a shunt malfunction until it is proved otherwise.

Intraoperatively, the shunt is tested for ventricular catheter flow and peritoneal catheter runoff; in addition, ventricular catheters that are adherent within the ventricular system are removed and repositioned. This will require judgment both as to how vigorous to be in removal of the old catheter and as to the technique to use in reinserting a catheter in a small ventricular system. We have found that a small neuroendoscope that fits within the ventricle is of great value in positioning the new catheter with a high accuracy rate.

With use of this primary focus on shunt function, our incidence of C2 M decompression has drastically decreased. On rare occasions (once in 7 years), a patient with refractory symptoms will have what appears to be a functioning shunt with progressive symptomatology. In that case, C2 M decompression is justified.

Once the decision is made to perform a C2 M decompression, spinal stability is again ensured with flexion–extension X-rays. The patient is positioned prone with the head held in a flexed position. We use a pin fixation device even in infants and young children; however, the clamp is tightened only enough to hold the head without significant tension being translated to the anterior fontanel. The head of the bed is elevated and the patient fixed to the bed.

An incision is made from the mid occiput to the lower extent of the herniated cerebellar vermis. This point is usually marked by a small bright enhancing mass representing the choroid plexus on enhanced MR imaging. In the patient with C2 M, the choroid plexus maintains its embryonic position at the outlet of the fourth ventricle and does not rotate into the roof of the fourth ventricle (► Fig. 16.12). The choroid marks the point of dissection for entering the fourth ventricle and is an important landmark. It is critical that the position of the torcular be assessed preoperatively. Frequently, the dural sinus system is low, sometimes approaching the foramen magnum. If the operator removes some occipital bone and opens the dura in the standard manner, it is entirely possible that a surgical misadventure will ensue. The amount of suboccipital bone that it is necessary to remove is usually small, and then only at the rim of the foramen. The dura is opened in the midline and the choroid plexus sought. The brainstem and upper spinal cord are frequently hyperemic from chronic displacement and ischemia. At times, the operator will confuse the bottom of the medullary kink for the opening into the fourth ventricle. Dissection between the kink and the upper cord should be avoided. On occasion, intraoperative ultrasound will be helpful in locating the ventricle and determining a point of entrance. Once the fourth ventricle is identified, the opening into it is performed, with visualization of the relatively avascular floor of the fourth ventricle. Again,

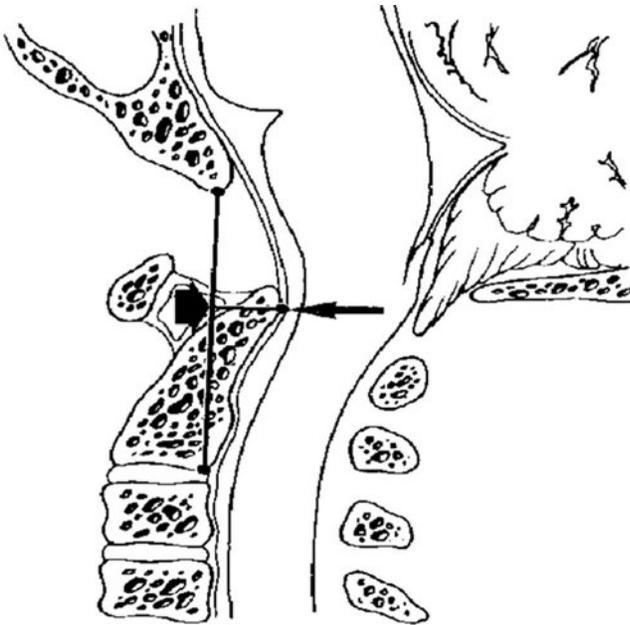

Fig. 16.12 Schematic drawing showing how we have quantified ventral compression in Chiari 1 malformation. (Grabb PA, Mapstone TM, Oakes WJ. Ventral brain stem compression in pediatric and young adult patients with Chiari I malformations. *Neurosurgery* 1999;44:520–552. Printed with permission.)

the dura is grafted with pericranial fascia. In planning for this decompression, one should minimize the bony removal in an attempt to avoid the postoperative kyphosis that is sometimes seen when a large syrinx is present in the cervical region.

These procedures are much more difficult than a standard C1 M decompression and are usually done in an infant or child who has serious neurologic compromise. The experience of the surgeon is especially important in minimizing complications and ensuring an adequate decompression.

16.4.3 Complications of Surgery

Chiari 1 and 2 Decompressions

Posterior fossa decompression is relatively safe but not without potential complications. Direct vascular and neural injury, pseudomeningocele, vascular lake bleeding, CSF leaks, and meningitis are well recognized. Less common complications include unrecognized occipital–cervical instability, acute postoperative hydrocephalus secondary to infratentorial hygromas, and anterior brainstem compression from a retroflexed odontoid.^{3,33} A complication unique to posterior fossa craniectomies is cerebellar slump or ptosis, which results from extending a craniectomy and dural grafting so far laterally and superiorly that the cerebellum herniates through the craniectomy defect. Cranioplasty to buttress the cerebellum into place is the most definitive treatment. Complications in our series of 500 patients were infrequent and included acute postoperative hydrocephalus requiring temporary external ventricular drainage and severe anterior brainstem compression requiring urgent transoral odontoidectomy. Meningitis or cerebellar slump was not observed.

There were no deaths. Recurrence of symptoms after a C2 M decompression is sometimes due to hydrocephalus or syringomyelia. Bone regrowth into the area of decompression may occur if the decompression is performed in very young children and has been associated with recurrent symptoms.³⁴

16.4.4 Results and Prognosis

Chiari 1 Malformations

The literature is replete with conflicting reports comparing variations of the posterior fossa decompression procedure for the C1 M. Without a large, long-term prospective study, no firm conclusion can be made regarding the different techniques. The likelihood of such a study appears remote given the relatively low incidence of the disease process, the relatively minor variations in technique, and the significant obstacles one encounters in organizing such a study. We are therefore forced to draw conclusions from our own experience and a review of the literature.

With an incomplete natural history, surgical data accumulated from a series of retrospective studies that claim to improve upon the natural history should be looked at cautiously. With an average of 7 years of follow-up, patients who presented with Valsalva-induced headache and neck pain had a very high likelihood of remaining asymptomatic.³ Children with symptomatic syringomyelia had a better than 95% likelihood of the syrinx remaining small or insignificant and the symptoms remaining stable or improved. In our series, this required a second procedure in the vast minority of patients with a syrinx. Scoliosis of more than 50 degrees, foot deformity, and other orthopedic changes involving bone generally remain the same. Children with neurologic deficits generally improve to a functionally normal status if operated upon in a timely manner. We again emphasize our prejudice for re-exploring the posterior fossa rather than performing myelotomy and any type of drainage of the syrinx.

Longer-term follow-up will need to be done to confirm these data, but in general the outlook for a child with a symptomatic C1 M is excellent. This implies appropriate patient selection. The adolescent patient with non-Valsalva-induced headache and a rounded 3-mm caudal descent of the tonsils does not have the same likelihood of complete resolution of the headache and pain after surgery.

Chiari 2 Malformations

The natural history of patients with this problem can be quite serious, with medullary symptoms still the leading cause of death in this population with treated myelomeningoceles. Early surgical intervention in a symptomatic infant or child is widely accepted, although only a few studies exploring the role of decompression in C2 M are available. Neonates and young infants displaying symptomatic C2 M require urgent evaluation and intervention. A more casual approach is likely to result in fixed deficits of swallowing and breathing. We cannot overstate attention to the function of the shunt; a simple comparison of the CT scans is inadequate in our view. Still, very young infants may do very poorly and succumb despite all efforts.

Pearls

- Although unique presentations of the Chiari 1 malformation occur, patients should be cautioned that surgical outcomes are less predictable.
- Valsalva-induced headache resulting in neck and occipital pain in this group is one of the most predictable preoperative symptoms to resolve following surgery.
- Posterior fossa decompression should occur in the midline and need not extend more laterally than the width of the foramen magnum.
- It is critical to avoid contamination of the subarachnoid space with blood during posterior fossa decompression.

17 Encephaloceles, Meningocele, and Dermal Sinuses

David F. Jimenez and Constance M. Barone

Substantive congenital anomalies exist that affect the craniofacial skeleton and represent defects in scalp, bone, meninges, and brain development. A wide spectrum is seen in the clinical setting, ranging from mild and nonvisible bony defects to severe cases of anencephaly (absence of the brain) and acrania (absence of the calvaria and brain). Anencephaly presents with acrania plus protrusion of a significant portion of the brain covered with a highly vascular epithelium that is tightly adherent to the underlying cerebral tissue. Amniotic bands in utero are thought to wrap around the cranial base, causing disruption of normal growth and leading to exencephalus and “nonanatomical” encephaloceles. Encephaloceles are a group of malformations characterized by calvarial and dural defects with extracranial herniation of leptomeninges, brain, and cerebrospinal fluid (CSF). In meningocele, the calvarial defect is associated only with the herniation of leptomeninges and CSF. Cranium bifidum occultum is a midline or paramedian calvarial defect that is not associated with brain, meningeal, or CSF prolapse.

Encephaloceles and meningocele have a common genetic background, but they are distinctly different and separate entities. The various types of meningoencephaloceles differ considerably in pathology, clinical presentation, racial and geographic distribution, treatment plans, and prognosis. Our goal in this chapter is to present a concise and comprehensive review of these craniofacial anomalies.

17.1 Encephaloceles

17.1.1 History

The earliest recorded documentation of encephaloceles can be found in ancient sculptures and medieval art. These abnormalities were commonly depicted in individuals portrayed as demons and monsters. The earliest recorded descriptions can be credited to Forestus (1590).¹ A century and a half later, Friderici (1737)² published his findings of an autopsy performed on a stillborn with a severe form of Robert’s syndrome and associated anterior encephalocele. The first monograph on encephaloceles was written by Corvinus in 1749.³ The pathogenesis of nasal frontal encephaloceles has been a subject of debate and controversy over the years. Multiple theories have been proposed to explain the development of these congenital anomalies.

In the 19th century, Saint-Hillaire (1827)⁴ published a theory based on experimental work on chicken embryos. He proposed that adhesions resulting from intrauterine pressure caused a malformation known as *hernie du cerveau* (“hernia of the brain”) to form between the brain anlage and germinal membranes, which led to an arrest in the development of the anterior cranial vault. Herniation of the brain thus occurs through this pathologic opening (► Fig. 17.1).

Several years later, Himly (1829)⁵ and Serres (1832)⁶ proposed that hernias formed through normally present bony channels, as opposed to a mild developmental formation through abnormal bony slits. In 1854, Spring⁷ hypothesized that encephaloceles arose as a consequence of various forms of ventricular dilation. In 1850, Rokitansky⁸ theorized that “congenital

herniation of the brain was caused by an extreme increase in organ bulk.” In 1868, Klementowsky⁹ proposed that these congenital anomalies were secondary to bone-related pathologic processes such as cranial tabes, rickets, and syphilis. Ankermann¹⁰ in 1882 continued to attribute these lesions to hydrocephalic states. Schmidt¹¹ in the 1900s blamed olfactory bulb remnants as the primary cause of encephaloceles (► Fig. 17.2a,b).

17.1.2 Classification

Several classification schemes have been proposed by multiple authors in the past, leading to confusion in the nosologic categorization of the lesions.^{12–17} A currently well-accepted classification is based on the anatomical location of the skull defect.¹⁸ Primary encephaloceles are those lesions that either are present at birth or have a congenital substrate. Secondary encephaloceles are acquired lesions that are most commonly the result of trauma or surgery.

Primary encephaloceles are divided into three major types: cranial vault, frontoethmoidal, and basal. Cranial vault encephaloceles can occur anywhere in the skull, and in North America they most commonly present in the occipital region (see box “Classification of Encephaloceles (p.206)”). Atretic encephaloceles are forme fruste encephaloceles; they characteristically

present as small, noncystic nodular or flat lesions located in the midline near the vertex (parietal type) or anterior to the inion (occipital type) (► Fig. 17.3, ► Fig. 17.4a,b). The overall incidence of encephaloceles is approximately 0.8 to 3.0 per 10,000 live births,^{19–22} and when compared with their spinal counterparts, encephaloceles account for approximately 10 to 20% of all cases of craniospinal dysraphism. Encephaloceles comprise approximately 10 to 15% of all neural tube defects.

17.1.3 Epidemiology

The incidence of encephaloceles varies worldwide with geographic location and race.²³ Occipital encephaloceles are the most common type in North America and western Europe, with an incidence varying between 1 in 3,000 to 1 in 10,000 live

births; they comprise ~85% of all encephaloceles.^{24–26} Seventy percent of occipital encephaloceles occur in females, and 15 to 20% are found in association with neural tube defects.^{27,28} In contrast, anterior encephaloceles occur with greater frequency (1 in 3,500 to 1 in 5,000 live births) in Southeast Asia (Thailand, Indonesia, Burma, Philippines, Malaysia), parts of Russia, and central Africa.^{23–33} The incidence of anterior encephaloceles in North America is estimated to be 1 in 35,000 live births. Basal encephaloceles are much less common and comprise fewer than 10% of encephaloceles.³⁴ Temporal encephaloceles are extremely rare malformations and are thought to comprise fewer than 1% of cerebrospinal malformations.^{35–37} The true incidence of encephaloceles secondary to trauma or surgery is not known.

17.1.4 Associated Anomalies

An encephalocele may present as a single isolated congenital anomaly or in association with other anomalies to comprise a syndrome or association (► Table 17.1).²⁸ Encephaloceles are most commonly associated with Meckel syndrome and amniotic band syndrome.³⁸ Meckel syndrome consists of occipital encephaloceles, polydactyly, polycystic kidneys, holoprosencephaly, micro-ophthalmia, retinal dysplasia, cardiac anomalies, orofacial clefts, and other anomalies. Occipital encephaloceles were found to occur in 39 of the 49 cases tabulated by Meckel and Passarge.³⁹

Amniotic band syndrome occurs because of amniotic tissue bands that form in utero and lead to the constriction of fetal parts and disruption of normal development (► Fig. 17.5). Most commonly affecting limbs or digits, these bands can become directly attached to the cranium or face, producing “nonana-

(b) Scalp marks for proposed incision to resect an atretic encephalocele. No spinal fluid is associated with this lesion, which was fully resected with excellent long-term effects.

Table 17.1 Syndromes associated with encephaloceles

Syndromes	Prominent Features	Etiology
Occipital encephaloceles		
Meckel syndrome	Polydactyly, polycystic kidneys, holoprosencephaly, micro-ophthalmia, retinal dysplasia, cardiac anomalies, orofacial clefts, ambiguous external genitalia, other abnormalities	Autosomal-recessive
Pseudo-Meckel syndrome	Arrhinencephaly, absent corpus callosum, Arnold-Chiari defect, no evidence of retinal dysplasia, cleft palate, congenital heart defects, accessory spleen, clubfoot, hallux hammer toes	t(3p+)
Chemke syndrome	Hydrocephaly, agyria, absent cortical laminar structure, cerebellar dysgenesis, retinal dysplasia, corneal opacities, cataracts	Autosomal-recessive
Cryptophthalmos syndrome	Extension of forehead skin to cover one or both eyes, unusual hairline, ear anomalies, notching of the nasal wings, soft tissue syndactyly of hands and/or feet, genital anomalies	Autosomal-recessive
Knobloch syndrome	High myopia, vitreoretinal degeneration, retinal detachment, meningocele, normal intelligence	Autosomal-recessive (presumed)
von Voss syndrome	Aplasia of the corpus callosum, hypoplastic olives and pyramids of the medulla oblongata, phocomelia, urogenital anomalies, thrombocytopenia	
Warfarin syndrome	Nasal hypoplasia, bone stippling, limb shortening, low birth weight, optic atrophy, mental retardation, seizures, hydrocephaly	Warfarin during pregnancy
Frontal encephaloceles		
Frontonasal dysplasia	Ocular hypertelorism, widow's peak, anterior cranium bifidum occultum, widely set nostrils with lack of elevation of the nasal tip, notching of nostrils, other abnormalities	Most cases sporadic, some familial, probably etiologically heterogeneous
Amniotic band syndrome	Ring constrictions and amputations of digits or limbs, distal syndactyly, irregular or asymmetric encephaloceles, microcephaly, micro-ophthalmia, bizarre orofacial clefts, other facial disruptions, tissue bands, various other anomalies	Aberrant tissue bands

tomical” encephaloceles. The lesions are unusual because they have irregular surfaces, are asymmetrically placed with respect to the midsagittal plane, and have multiple sites of involvement (► Fig. 17.6, ► Fig. 17.7, ► Fig. 17.8, ► Fig. 17.9). Chemke syndrome is characterized by occipital encephaloceles, hydrocephalus, agyria, retinal dysplasia, corneal opacities, and cataracts.⁴⁰ Cryptophthalmos syndrome involves extension of the forehead skin to cover one or both eyes, unusual hairline, ear abnormalities, notching of the nasal wings, soft tissue syndactyly of hands and feet, genital anomalies, and a 10% incidence of occipital encephaloceles. It is inherited as an autosomal-recessive trait. Knobloch syndrome presents with myopia, vitreoretinal degeneration, retinal detachment, and occipital meningoceles.⁴¹ von Voss syndrome involves aplasia of the corpus callosum, hypoplastic olives and pyramids of the medulla, phocomelia, urogenital anomalies, thrombocytopenia, and occipital encephaloceles. Warfarin syndrome has been associated with the ingestion of warfarin during pregnancy. It presents with nasal hypoplasia, bone stippling, limb shortening, low birth weight, optic atrophy, mental retardation, seizures, hydrocephalus, and occasionally occipital encephaloceles.

Associated anomalies (see box “Associated Anomalies Seen in Patients with Encephaloceles (p.208)”) include absence of the corpus callosum, optic nerve abnormalities, cleft lip, cleft pal-

ate, Tessier facial clefts, craniosynostosis, Dandy-Walker cyst, Chiari malformations, ectrodactyly, hemifacial microsomia, hypertelorism, Klippel-Feil anomalies, myelomeningoceles, and anophthalmia.³⁸ Hydrocephalus is relatively common in patients with occipital encephaloceles, and the incidence may be as high as 65% (► Fig. 17.7).⁴² In contrast, hydrocephalus is seldom seen in patients with nasofrontal encephaloceles.

17.1.5 Occipital Encephaloceles

The etiology of occipital encephaloceles is not well understood, but these anomalies have been correlated with maternal low-folate levels and the use of vitamin A and sodium arsenate. In North America, occipital encephaloceles are the most common type seen clinically and account for approximately 80% of these lesions. The diagnosis is now commonly made with routine prenatal ultrasonography, which helps guide the treatment plan. Given the common association of multiple intracranial anomalies, complete examination of the patient's cranial vault and cervical spine should be undertaken with magnetic resonance (MR) imaging. Although the diagnosis of occipital encephalocele is usually obvious at birth, subtle brain herniations may require a high level of suspicion. Occipital encephaloceles can be located high in the occipital squama or lower at the level of the foramen magnum level; they may even involve the upper cervical spinal levels.

Clinical Presentation

The presence of an occipital encephalocele is obvious at the time of birth, and many of these lesions are now being diagnosed in utero with ultrasonography. Vaginal delivery may be possible with relatively small lesions, whereas larger encephaloceles may necessitate cesarean section. The clinical presentation may vary significantly, depending on the size and contents of the lesion. Infants who have small encephaloceles with little or no herniating brain may act normally, with adequate breathing and normal neurologic examinations. Almost all lesions are fully covered with skin and can be electively repaired. Larger masses may be associated with neurologic deficits: cranial nerve abnormalities, poor sucking and

feeding, spasticity, blindness, and developmental delay. Patients may present with large sacs and microcrania. Associated neural tube defects may be seen in 15 to 20% of the patients.¹⁶ Reported associated congenital malformations include hypoplastic left cranium, bilateral clinodactyly, web neck and micrognathia, thyroglossal cyst, and external annular dermoids.⁴²

Pathology

Encephaloceles are believed to result from the failure of separation of the surface ectoderm from the neuroectodermal elements. The result is a bony defect in the skull that permits herniation of neural elements as well as CSF. The pathology of these lesions directly correlates with their site and location. Small lesions, located in the subtorcular area, may have only CSF and gliotic nonfunctional tissue. Larger masses with bony defects involving the entire occiput and upper cervical levels may have massive infra- and supratentorial brain herniation. The sites of encephaloceles vary significantly. They are often large: larger than 20 cm (16%), 15 to 20 cm (14%), 10 to 15 cm (12%), 5 to 10 cm (30%), and smaller than 5 cm (28%).⁴² The occurrence of associated hydrocephalus varies with published series: 16%,⁴² 36%,²⁵ 50%,⁴³ and 65%.⁴⁴ The skull base may be deformed, and microcephaly has been reported in from 9 to 27% of cases.²⁰ The falx and tentorium are often in an abnormal anatomical position. Bony defects may also vary in size and extent; they may involve just the occipital bone or may include the posterior elements of adjacent vertebrae and even extend superiorly, above the inion. The contents of the sac may be extremely variable. Simpson et al reported that 32% of the patients' lesions contained recognizable cortex, 11% contained cerebellum and fourth ventricular structures, and 20% contained glial nodules. The brainstem may be partially or completely herniated. Thalami were found in 20% of the cases.²⁸ Postmortem examinations^{24,27} have revealed multiple abnormalities, including a small posterior fossa, hypoplastic falx and tentorium, and asymmetric herniation of the cerebral hemispheres ranging from an occipital pole to an entire hemisphere (see box "Associated Findings in Patients with Occipital Encephaloceles (p.211)"). The intracranial contents tend to shift posterocaudally, leading to frontal lobes occupying variable portions of the middle fossa and temporal lobes partially displaced into the posterior fossa (► Fig. 17.10a,b). Notable distention of the ventricular system, optic pathways, corpus callosum, and hypothalamus has been noted. The posterior fossa shows the most remarkable anomalies, with marked brainstem distortion that is often seen as an s-shaped kink (► Fig. 17.11). The cerebellum may be rudimentary and associated with cleftlike fissures extending into the dorsal brain stem from the fourth ventricle. The "inverse cerebellum" described by Padgett⁴⁵ shows ventral protrusion of the cerebellar hemispheres to envelop the anterior lateral aspects of the brainstem, with vermian agenesis or hypoplasia and brainstem kinking. The fourth ventricular roof opens into the sac, leading to a "fourth ventriculocele."

Prognostic Factors and Outcomes

The prognosis and long-term outcome for patients born with occipital encephalomeningoceles are directly proportioned to the amount of neural tissue found in the sac and the severity of the associated neural anomalies. The infant who has only CSF or small nodules of dysplastic neural tissue in the sac has a relatively good chance of attaining normal or nearly normal neurologic and physical development. Patients with few anomalies and a small amount of neural herniation will have approximately a 53% chance of being physically and mentally normal, a 28% chance of normal intelligence but physical impairment, and a 19% chance of mental retardation.²² Conversely, the greater the neural involvement and number of associated neural

abnormalities, the greater the rate of mental retardation and poor outcomes. When all patients with occipital encephaloceles are considered, approximately 17% will be normal and 83% will be significantly mentally and physically impaired.²² The appropriate treatment of hydrocephalus plays an important role in the long-term outcome of these patients.⁶⁶

Surgical Treatment

Unless the sac has ruptured and there is concurrent leakage of CSF, surgical repair may be done electively (► Fig. 17.13). The patient is placed prone on an appropriately padded cerebellar horseshoe headrest (► Fig. 17.14a). A single dose of an antibiotic (first-generation cephalosporin) is given before induction. The occipital and upper cervical areas are prepared and draped, with application of povidone-iodine solution. If a large sac is present, it may be elevated with grasping forceps by an assistant to allow complete skin preparation. Using a very low-level (15-W) monopolar electrocautery, the surgeon creates a plane of dissection between the junction of “normal” skin and epithelialized skin. This plane is carefully followed circumferentially and toward the neck of the encephalocele (► Fig. 17.14b,c). A transverse incision is extended to expose the underlying bone and bony defect. A dissection plane is developed between the dura and the skin. Entrance into the dome of the sac will allow CSF to drain and the contents of the sac to be explored. At this point, careful examination of the encephalocele should help guide the surgeon on the proper surgical approach. If the herniating mass is deemed to be composed of fibrous, gliotic, nonfunctional tissue, a decision to transect the mass flush with the skull can be safely made. Some authors have advocated “expansion cranioplasties” to accommodate large amounts of herniated neural tissue. If the herniated tissue is deemed “viable” or resembles normal cerebral architecture, it should be saved, and the expansion cranioplasty technique should be employed.

Fig. 17.13 Newborn female infant with a very large occipital encephalocele.

Barrel stave osteotomies can be created with a drill and expanded outward. The open end of the encephalocele can then be covered with full-thickness calvarial grafts from the surrounding parietal bones (► Fig. 17.15a–c). This maneuver will provide complete osseous coverage of the encephalocele area. However, it should be done only in young infants who are fully capable of regenerating new calvarial bone at the donor site. Another technique uses tantalum mesh to create an extracranial compartment to enclose the neural elements.⁴⁶ The mesh is attached to the periphery of the skull defect. As the intracranial pressure increases, the calvaria is forced to expand, and the mesh is gradually imbricated with the skull by daily digital compression. Another approach is simply to close soft tissues over the neural mass and perform a revision as a second stage.⁴³ A ventricular volume reduction technique has been proposed by Oi et al⁴⁷ to deal with this problem. Using the associated hydrocephalic state, they do a first-stage procedure that involves closing the encephalocele defect with a dural patch graft. The repaired dura allows the intraventricular pulse pressure to produce ventriculomegaly. Once hydrocephalus develops, a ventriculoperitoneal shunt is placed to allow transposition of the herniated brain into an enlarged intracranial cavity.⁴⁸ However, despite attempts at preserving neural tissue by these techniques, profound morbidity continues to be associated with large occipital encephaloceles.

If the skull defect is small (pedunculated encephalocele), no specific management of the bone defect is necessary. Whenever large calvarial defects are present, a simple way to manage them is to extend the skin opening into adjacent parietal regions. A full-thickness craniotomy fitting the shape of the skull defect may be harvested and transposed. The donor site contains osteogenic dura that will ossify and create new bone within 2 to 6 months (► Fig. 17.16a–f). Another acceptable method for dealing with large calvarial defects is to close the encephalocele first, and then later (when the child is about 2 years old) proceed to an autologous cranioplasty with a split-thickness calvarial graft. Hydroxyapatite bone cement (Bone Source; Howmedica Leibinger, Dallas, TX) is commercially available for the closure of cranial defects up to 25 cm.¹³ The cement is composed of tetracalcium phosphate and dicalcium phosphate powder reactants that, when mixed with water, lead to the isothermic formation of a solid implant composed of carbonated hydroxyapatite. This compound has been used successfully to reconstruct posterior fossa calvarial defects⁶⁸ and perhaps should be considered for reconstructing small encephalocele defects in selected patients. Yet another method for closing a skull defect associated with an encephalocele involves the use of HTR-PMI, which is a combination of PMMA (poly-methylmethacrylate) and PHEMA (poly-hydroxyethylmethacrylate) and has a rigidity similar to that of bone (W. Lorenz Surgical, Jacksonville, FL). A proprietary computed tomographic (CT) scan protocol is used to produce a custom-fitting implant.

17.1.6 Anterior Cranial Fossa Encephaloceles

Various classifications have been proposed for categorizing encephaloceles located in the anterior cranial fossa. Sincipital encephaloceles are those lesions that are associated with the skull

Care must be taken not to allow the encephalocele to move inadvertently and cause torsion of the cerebral contents of the posterior fossa. (b) A plane of dissection is developed between the scalp and the encephalocele. A vascular scalp is often seen, and care must be taken not to violate the galea and cause significant blood loss. defect at the foramen cecum, anterior to the cribriform plate. Suwanwela and Suwanwela proposed the most useful and widely accepted classification of sincipital encephaloceles in 1972.¹⁸ They classified these lesions as nasofrontal, nasoethmoidal, naso-orbital, and interfrontal encephaloceles. Basal encephaloceles are those lesions that protrude through the floor of the anterior cranial fossa (cribriform plate, planum

sphenoidale). These lesions have been classified as sphenopharyngeal, sphenoorbital, sphenomaxillary, and sphenothmoidal.

Pathology

The pathogenesis of frontal encephaloceles is not known. Currently, two schools of thought exist regarding the origin of

these lesions. The first concept involves the point of weakness in the facial skeleton. The frontal bone is a membranous bone that forms from the underlying dura, whereas the ethmoid bone develops during endochondral bone formation. The function of the membranous and endochondral bone (foramen cecum is thought to result in a weak area through which the neural elements can herniate).^{43,44} A second hypothesis states that a delayed closure of the neural tube ultimately prevents normal union of the facial bones.⁴⁵ Findings of a trapped meningocele and peripheral nerve elements, as well as isolated neural tissue remnants along the original tract, appear to substantiate the second theory. However, the fact that most anterior encephaloceles are covered with normal skin indicates that

these defects are not simply a failure of neurulation. Thus, their precise etiology remains speculative. On histologic examination, the herniated tissue can vary between normal brain to fibrous atrophic nonviable tissue.⁴⁶ In the majority of cases, however, the herniating mass of a nasofrontal encephalocele consists of gliotic, nonfunctional neural tissue.^{21,31}

In contrast, occipital encephaloceles contain a much wider variety of tissue types. Simpson²⁰ reported that 32% of patients had recognizable cerebral cortex within the sac, 11% had cerebellum and fourth ventricle, and 20% had glial nodules. Oi et al⁴⁷ reported temporal lobe herniation, occipital lobe herniation, dysgenesis of the tectum, dysgenesis of the vermis, corpus callosum dysplasia, thalami fusion, brainstem kinking, and

cerebellar inversion as findings associated with occipital encephaloceles. Other authors have reported the presence of supratentorial cortex with or without herniation, cerebellar tissue, and fourth ventricular tissue (see box “Associated Findings in Patients with Occipital Encephaloceles (p.211)”). Disorganized fibrous and vascular tissue was also commonly found in many patients with occipital encephaloceles.^{24,27,48}

17.1.7 Sincipital Encephaloceles

Clinical Presentation

The clinical presentation of a sincipital encephalocele can range from an occult, nondiscernible lesion to marked craniofacial deformity (see Box Signs and Symptoms of Sincipital Encephalo-

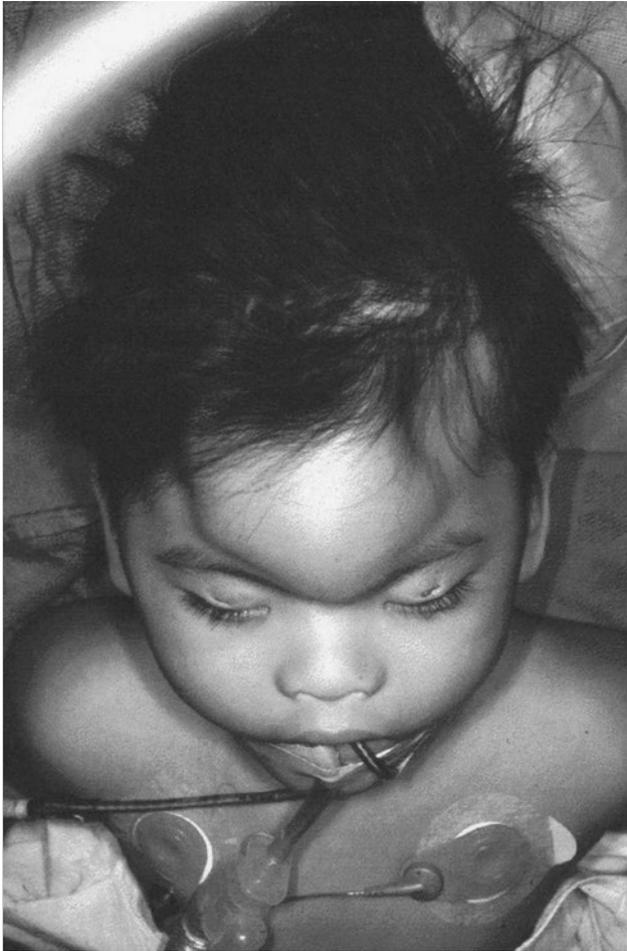

Fig. 17.17 A 2-year-old boy with a large protruding forehead mass secondary to an interfrontal encephalocele.

loceles (p.216)). A sincipital encephalocele may vary in size from a barely noticeable mass to a lesion larger than the patient's head.

Signs and Symptoms of Sincipital Encephaloceles

- Large forehead mass
- Nasal/nasional mass
- Hypertelorism
- Telecanthus
- Orbital dystopia
- Unilateral micro-ophthalmos or anophthalmos
- Epiphora

Interfrontal Lesions

Patients present with a midline forehead mass that may be soft and pulsatile; it may be small, or it may be large, involving most of the forehead. The skull lesion is located between the nasion and the bregma, and the lesions may be simple or complex and associated with other cranial anomalies (► Fig. 17.17, ► Fig. 17.18, ► Fig. 17.19).

Nasofrontal Lesions

The herniated tissue extends through the body defect at the midline junction between the frontal and nasal bones. The mass may be seen as a small protuberance at the nasion (► Fig. 17.20) or as a larger mass extending forward and laterally to displace the nasal bones inferiorly and the medial walls laterally (► Fig. 17.21). Extension to the nasal passages can cause obstruction. (► Fig. 17.22, ► Fig. 17.23)

Nasoethmoidal Lesions

This type of encephalocele also has a cranial defect at the level of the foramen cecum; however, the herniating mass extends anteroinferiorly and passes between the nasal bones and the nasal cartilage and then extends to the surface between the structures (► Fig. 17.24). Similar to other encephaloceles, the protruding lesion may be relatively small or very large (► Fig. 17.25).

Naso-orbital Lesions

In this type of encephalocele, the mass extends inferolaterally through the frontal ethmoid junction and into the nasion and

orbital areas, at the level of the middle third of the frontal process of the maxilla. These lesions cause orbital deformities: lateral displacement of the globe, upward or downward displacement of the globe (vertical dystopia) (► Fig. 17.26), telecanthus, and damage to the nasolacrimal duct leading to epiphora and dacryocystitis. Ocular deformities range from decreased global motility to hypothalamic coloboma of the

optic nerve, and even anophthalmia (► Fig. 17.27).^{28,46} Basal encephaloceles do not have the obvious clinical characteristics of sincipital lesions. As previously described, these lesions are classified according to the location of the bony defect and extension of the herniated mass. Transethmoidal lesions have a bony defect at the level of the cribriform plate and extend through the ethmoid sinuses into the anterior aspect of the nasal cavity. Sphenoethmoidal lesions extend

through defects in the posterior aspect of the cribriform plate at the junction with the sphenoid bone and extend into the posterior nasal cavity; transsphenoidal encephaloceles extend into the epipharynx or the sphenoid sinus.

Fig. 17.27 A 7-year-old patient with a nasofrontal encephalocele. Note extension of the mass into the right orbit along with inferior and lateral displacement of the globe. Ocular motion was significantly restricted.

Spheno-orbital encephaloceles extend into the orbit via the superior orbital fissure and may present with proptosis and exophthalmos. In the majority of cases, these lesions present with characteristics that help differentiate encephaloceles from nasal polyps; for example, (1) encephaloceles tend to occur in children, whereas polyps are more common in adults; (2) encephaloceles are located in the midline, medial to the middle concha, whereas polyps are located lateral to the middle concha; and (3) encephaloceles are firmly attached to the medial surface of the septum, whereas polyps tend to be pedunculated and laterally located.²² A positive Furstenberg sign (visible swelling and pulsation of the mass with jugular venous compression) will indicate the presence of an encephalocele. Polyps do not swell or pulsate.

Diagnostic Studies

At the present time, CT and MR imaging are the diagnostic tests of choice, and they have supplanted all other tests. CT scans (axial, coronal, and sagittal reconstructed images) are indispensable for ascertaining the extent and location of the cranial defects (► Fig. 17.28).⁴⁹ Brain algorithms allow an accurate determination of whether CSF or gliotic tissue is present within the sac. However, triplanar MR images are the gold standard for ascertaining the extent of neural herniation. MR images are necessary for the complete visualization of basal encephaloceles, particularly those associated with the herniation of hypothalamic or diencephalic masses. MR angiography is valuable in assessing the vasculature associated with deeply located encephaloceles. Because sincipital encephaloceles are not commonly

Fig. 17.28 Axial computed tomographic scan of a patient with a sincipital encephalocele extending into the nasofrontal area.

associated with major vascular anomalies, there is no role for cerebral angiography in the diagnostic work-up of patients with these lesions.

Surgical Treatment

A variety of surgical approaches have been proposed for the surgical treatment of sincipital encephaloceles.^{50-61,63-65} These can be divided into two major categories: intracranial and extracranial. The timing of surgery also varies, but unless there is CSF leakage, sincipital encephaloceles can be treated electively. Ideally, these lesions should be treated early in infancy to prevent the deleterious secondary effects of an enlarging encephalomeningocele on craniofacial structures. The goals of the surgical treatment of sincipital and frontal encephaloceles include the following: (1) resection of the herniated mass flush with the floor of the anterior cranial fossa; (2) adequate repair of the dural defect with a pericranial patch graft; (3) prevention of postoperative CSF leakage; (4) correction of hypertelorism, if present; (5) reconstruction of the nasal elements, if necessary; (6) alignment of the horizontal ocular axis with medial cantho-pexy; and (7) cannulation of obstructed nasolacrimal ducts. Properly trained craniofacial teams can achieve all these goals with minimal morbidity and without mortality. Extension of these lesions into the facial skeleton requires the input of craniofacial surgeons to obtain the best possible results.

Although some authors have advocated two-stage procedures, the current method of choice involves a single operation. The neurosurgical team will resect the encephalocele and close the dural and cranial defects, and the plastic surgery team will proceed with craniofacial reconstruction of the defect, hypertelorism correction (if needed), nasal reconstruction, and dermal closure.

Our preferred method of treatment for these encephaloceles consists of the use of a minimally invasive craniotomy (nasional craniotomy) that is located below the bregma and involves the removal of a small rectangular piece of bone extending from the level of the eyebrows down to the tip of the nasal bone. After the area is exposed with a bicoronal scalp flap, a drill (Midas Rex C1 bit; Medtronic Neurosurgical, Goleta, CA) is used to create the osteotomies. Following removal of the bone, the dura and base of the herniating encephalocele are exposed. Transection of the gliotic brain is made along a line parallel to the cribriform plate. The herniated tissue can then be removed from the orbits, maxilla, and nasal cavities. A vascularized pericranial flap can be brought down to the empty cavities in order to obliterate dead space and seal it from the cranial cavity. A vascularized or free pericranial graft is used to close the dura along the cribriform plate area. A small piece of split calvarial graft can be used for reconstruction of the bone defect of the anterior cranial fossa. A long rectangular strip of full-thickness or split-thickness calvarial bone can be used as a cantilever graft to reconstruct the bridge of the nose. The presence of telecanthus can be corrected with the use of wire to reduce and medialize the medial canthal ligaments. Closure of the bicoronal scalp flap can be done in a standard fashion with absorbable galeal sutures and scalp staples.

Prognostic Factors and Outcomes

Advances in surgical techniques and anesthetic management currently allow the performance of major craniofacial operations without intraoperative mortality or major complications.

The majority of patients with nasofrontal encephaloceles have normal or nearly normal intelligence and ultimately do well following the repair of their congenital deformity. These operations are well tolerated by the patients if the surgical team ensures proper preoperative screening and medical preparation. Review of our experience following the treatment of 42 patients with sincipital encephaloceles reveals no intra- or postoperative mortalities. Morbidities were confined to dacryocystitis ($n=2$), superficial cellulitis ($n=1$), and CSF leak ($n=1$). Care must be taken to ascertain the patency of the nasolacrimal duct before surgical correction of the encephalocele. If the ducts are found to be blocked, cannulation of the duct system should be undertaken. If cannulation is unsuccessful, a dacryocystorhinostomy should be considered (► Fig. 17.29 and ► Fig. 17.30). Failure to achieve duct patency will place the patient at an increased risk for dacryocystitis during the postoperative period.

Fig. 17.31 Aerial view of a bicoronal scalp flap demonstrates improper location of a craniotomy. Demarcated area shows a unilateral location of the craniotomy. The high location of the bony opening did not allow the surgeon adequate access to the midline nasoethmoidal encephalocele.

Published mortality rates of patients operated on for frontal encephaloceles vary between 7 and 20%.^{20,62} These reports, however, are older and do not represent the current low mortality rate (< 1%) achieved at most craniofacial centers.

Management Pitfalls

Difficulties may arise in the management of these patients in North America because of the very infrequent presentation of sincipital encephaloceles (1 in 35,000 live births). As such, the average neurosurgeon or plastic surgeon may see only one or two patients with sincipital encephaloceles in a professional lifetime. Therefore, we believe these patients should be referred to craniofacial centers with experience in treating the complex lesions. Having surgically managed several patients referred after improper resection of these masses, we have identified several potential pitfalls in their management.

Inadequate Exposure

Improper placement of the bone flap may lead to the inability to completely resect the encephalocele. A unilaterally highly placed craniotomy (► Fig. 17.31) will not allow proper access to the lesion. Although a properly placed unilateral craniotomy may give access to the lesion, a bifrontal approach is preferable. Difficulty in properly exposing the lesion may arise when a bifrontal craniotomy is placed too high above the supraorbital rims.

Inadequate Resection

An improperly approached encephalocele may not be fully resectable. If this occurs, the patient will continue to show a facial mass, which is a poor postoperative result (► Fig. 17.32 and ► Fig. 17.33).

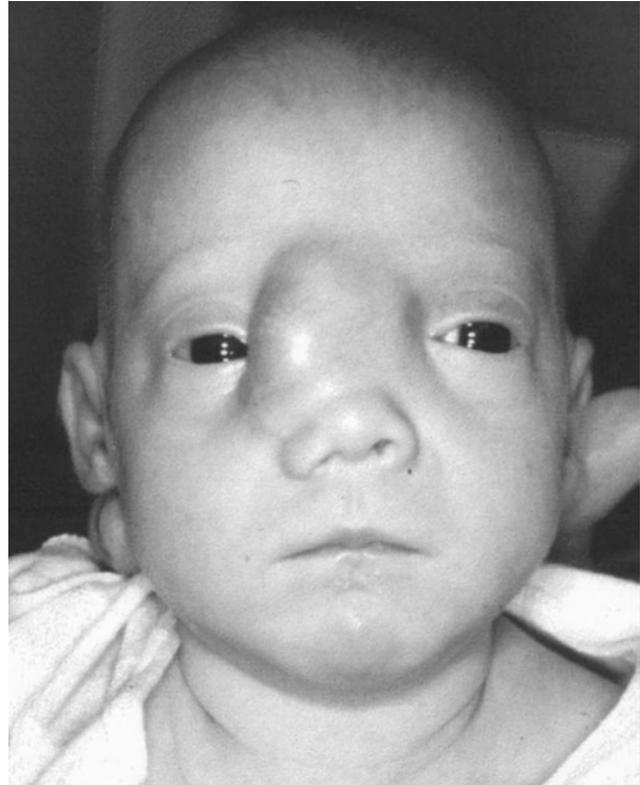

Fig. 17.32 A 1-month-old premature girl whose original repair resulted in residual encephalocele and the postoperative development of a pseudomeningocele. Note the inferior displacement of the nasal ala secondary to fluid buildup.

Improper Closure

This can lead to postoperative CSF leaks or pseudomeningocele formation. The use of spinal drains and/or fibrin glue significantly reduces the risk.

Insufficient Preoperative Preparation

All patients should be fully evaluated by the craniofacial team; extensive medical (pediatric), ophthalmologic, dental, neurologic, and radiologic evaluations should be performed. Failure to identify hydrocephalus will lead to postoperative CSF leaks and wound dehiscence and/or infections. All medical abnormalities (anemia, infections, malnutrition, others) should be corrected before surgical treatment. In developing countries, care should be taken to eliminate any parasitic infection that may be present preoperatively.

17.1.8 Basal Encephaloceles

Basal encephaloceles (transsphenoidal, sphenoethmoidal, transtethmoidal, and spheno-orbital) are uncommon in Western countries, making up approximately 5% of all encephaloceles. These lesions are located in the anterior skull base and may extend through bony defects in the ethmoid bone, ethmoid-sphenoid junction, or sphenoid bone. The encephalocele mass may

extend into the ethmoid sinus and into the nasal cavity or through the sphenothmoid junction or sphenoid sinus into the epipharynx. The clinical presentation is such that the patient is often brought to an otolaryngologist because of a nasal or epipharyngeal mass associated with noisy, difficult breathing; recurrent upper respiratory infections; nasal discharge; recurrent meningitis; and occasional CSF leaks (especially after a “nasal polyp” biopsy) (► Fig. 17.34, ► Fig. 17.35). Clinical examination most often reveals a mass covered with mucosa in the nasal or epipharyngeal cavities, usually located in the midline and associated with a positive Furstenberg sign. Spheno-orbital encephaloceles present with progressive pulsating exophthalmos and a defect on the sphenoid bone leading to intraorbital herniation. This type of encephalocele may also reach the orbit via the superior orbital fissure. Associated ocular abnormalities include progressive visual loss, micro-ophthalmos, coloboma, hydrophthalmos, anophthalmos, and microcornia.¹¹

Treatment

The goal of treatment is to obtain a watertight dural closure of the defect following amputation of the mass or its relocation into the cranial cavity. These lesions are much more difficult to treat, given the propensity of vital structures (hypothalamus, anterior cerebral arteries, optic nerves, optic chiasm, third ventricle) to herniate. Extracranial approaches

are associated with many problems, including incomplete resection and postoperative CSF leaks. The intracranial approach is the preferred method of treatment. If the stalk is narrow, intradural exploration will allow proper amputation of the lesion and adequate dural repair with autologous pericranium. If the neck of the lesion is wide and normal structures are suspected to be herniated, every attempt should be made to relocate the vital structures into the cranial cavity. When a lesion is located in the ethmoid or planum sphenoidale, a bifrontal craniotomy will afford excellent access to the encephalocele. Additional extension laterally (pterional craniotomy) or temporally (subtemporal craniotomy) may be desired for lesions extending into the orbit or the infratemporal fossa. Following adequate amputation and dural closure, often the extracranially herniated tissue is not resected but rather allowed to shrink without the necessity for a second operation. The prognosis of patients with basal encephaloceles is usually excellent except for those in whom vital structures have massively herniated. The prognosis is better than that for occipital or parietal encephaloceles. As with other types of encephaloceles, proper preoperative evaluation, planning, and surgical corrective procedures are essential for obtaining a successful outcome, including use of endoscopic technique.⁶⁷

17.1.9 Cranial Vault Encephaloceles

In addition to nasofrontal and occipital areas, encephaloceles may also arise from the parietal and temporal bones. Parietal encephaloceles are relatively uncommon, although in some series the incidence has varied between 12.5⁶⁹ and 37.5%.⁷⁰ McLaurin⁷¹ presented 13 patients with intraparietal encephaloceles. Four of them had agenesis of the corpus callosum, three had communication of the lateral ventricles with a surface lesion, and two had Dandy-Walker cysts. He reported a highly unfavorable prognosis in these patients with parietal encephaloceles. Simpson⁹ reported 13 patients with parietal encephaloceles, four of which were associated with agenesis of the corpus callosum or holoprosencephaly. Yokota et al⁷⁰ reported 15 patients with parietal encephaloceles and also found that they carried a much less favorable prognosis than those in the occipital region, regardless of the type. This poor outcome was related to the accompanying cerebral malformations, which appeared to be more frequent and severe than those associated with encephaloceles in the occipital or frontal area. Associated anomalies with parietal encephaloceles in this series included massive cerebral herniation, Chiari 2 malformations, diencephalic cyst, vermis agenesis, corpus callosum agenesis, and midline porencephaly.

17.1.10 Temporal Encephaloceles

Encephaloceles can also occur in any area of the temporal bone. The true incidence of temporal encephaloceles is unknown. Wilkins et al⁷² categorized this type of encephalocele into five subtypes. Lateral temporal encephaloceles extend through a defect at the pterion or asterion. This lesion is apparent during early infancy and most commonly found in females. Anterior temporal encephaloceles present with a defect in the wing of the sphenoid, with herniation into the posterior orbital area

and unilateral pulsating exophthalmos. Anterior medial encephaloceles extend through a defect of the anterior wall of the middle fossa and into the sphenoid sinus. Patients may present with CSF rhinorrhea, or the lesions may be detected incidentally. Posterior temporal encephaloceles (aural) herniate through the tegmen tympani into the tympanic antrum or epitympanic recess. Patients present with CSF in the middle ear, rhinorrhea or otorrhea, decreased hearing, and occasional meningitis. Anterior-inferior temporal encephaloceles project through the anterior floor into the infratemporal fossa. Patients most commonly present with simple or complex partial seizures.⁷² Endaural encephaloceles of the middle fossa may be repaired from below (mastoidectomy) or from above (middle fossa craniectomy) or a combination of these.⁷³ Larger encephaloceles should be approached via craniotomy. When the encephalocele impinges on the ossicular chain, a combined tympanomastoid-middle fossa craniotomy approach is the procedure of choice.⁷⁴

A combination of brain MR imaging and CT can be used to provide the treating surgeon with the necessary anatomical knowledge to resect and reconstruct the encephalocele. Anterior or medial temporal encephaloceles can be approached with a standard pterional craniotomy. Posteriorly located lesions can be treated with a subtemporal craniotomy. As with other encephalocele types, the herniating brain should be amputated and resected.⁶⁸ The cranial defect is repaired with a customized split-thickness calvarial graft obtained from the approach craniotomy (► Fig. 17.36, ► Fig. 17.37). The dura can be repaired with a free pericranial graft. This surgical approach can lead to definitive and long-lasting correction of the condition with excellent results and minimal morbidity or complications.

17.2 Meningocele

Meningocele are lesions in which an underlying skull defect is associated with herniation of the leptomeninges and CSF.

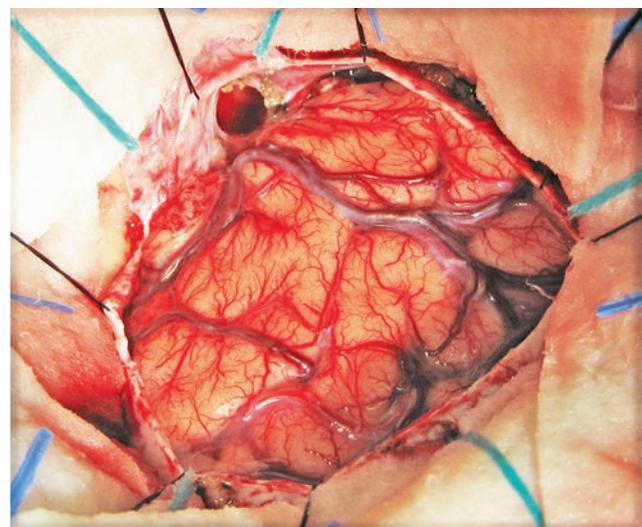

Fig. 17.36 Temporal fossa encephalocele. Craniotomy demonstrates a round bone defect on the floor of the middle fossa, through which a part of the inferior temporal lobe has herniated.

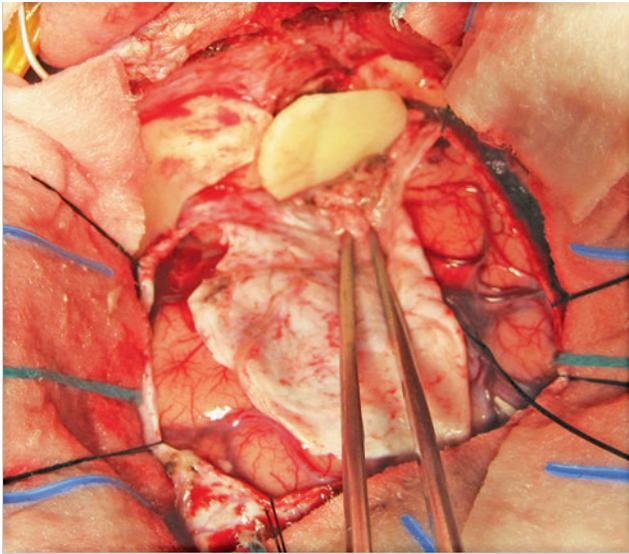

Fig. 17.37 After resection of the encephalocele, the temporal bone is reconstructed with a split-thickness calvarial graft. A vascularized pericranial graft is then used to further seal the defect.

Fig. 17.39 A 7-month-old child presented with an enlarging pulsatile mass over the area of the anterior fontanel. Surgical exploration revealed a simple meningocele without sinus involvement.

No neural tissue is found in these lesions (► Fig. 17.38). They are located anywhere that encephaloceles are encountered (► Fig. 17.39). Primary meningoceles are congenital in nature and typically present at an early age. Secondary meningoceles

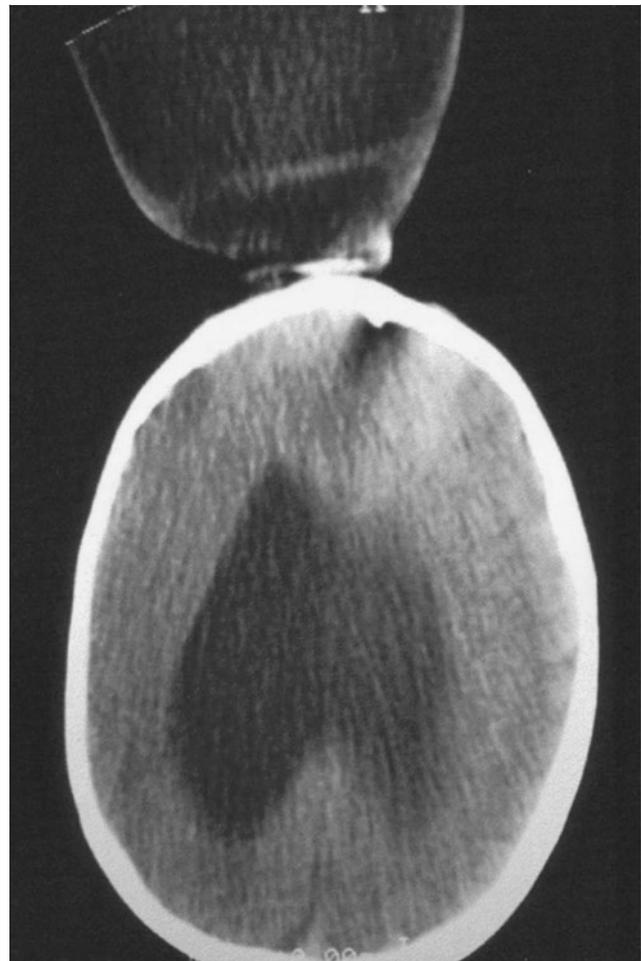

Fig. 17.38 A very large frontal meningocele in a 5-month-old child. No neural elements were found inside the sac. The patient required a shunt after closure of the meningocele.

are commonly due to postsurgical defects. They occur whenever a bone flap is removed and the dura is left open (as in decompressive craniectomies for malignant brain swelling) (► Fig. 17.40). The treatment includes closure of the dural layer, either primarily or with a dural substitute, in a watertight fashion. The skull defect is then closed with an autologous acrylic or hydroxyapatite cranioplasty. These lesions have a much better prognosis than encephaloceles.

17.3 Cranial Dermal Sinuses

Congenital cranial dermal sinuses are midline tracts lined by stratified squamous epithelium that extend between the superficial dermal layers and deeper cranial structures (see box “Signs and Symptoms of Cranial Dermal Sinus Tracts (p.225)”⁷⁵). The depth of extension is variable and may include central nervous system structures and their coverings. Given its internal architecture, the tract may expand anywhere along its length (particularly at either terminus) to form dermoid or, less commonly, epidermoid cysts. Although dermal sinuses can occur anywhere along the neural axis, in the cranial vault the majority (85%) are located in the occipital region near the inion,

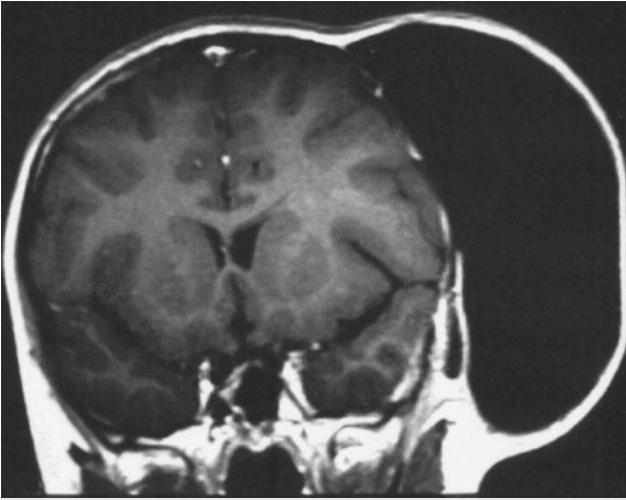

Fig. 17.40 T1-weighted coronal magnetic resonance image of a 12-year-old boy who underwent a craniotomy for evacuation of a subdural empyema. The bone flap was left out, and the dura opened as a result of massive brain swelling. This acquired meningocele contained 510 mL of cerebrospinal fluid and subsided with replacement of the bone flap.

11% in the frontal region (nasion and nasal structures),^{11,76,77} and 5% in the posterior parietal area. Eighty-nine percent of dermal sinuses are associated with inclusion tumors; dermoid cysts are the most common type. Eighty-two percent are found to extend subdurally or deeper, and 18% are found to be purely extradural.⁷⁸

Signs and Symptoms of Cranial Dermal Sinus Tracts

- Midline facial or occipital dimple
- Nasal mass
- Long, fine, black hairs and a dimple
- Recurrent meningitis
- Drainage from the dermal pit

17.3.1 Pathology

Nasal dermal sinus tracts result from an alteration of the embryologic development of the nasofrontal region. To better understand the genesis of these lesions, we present a brief review of the normal sequence of events. Concurrently with closure of the anterior neuropore at approximately 24 days of gestation, mesodermal tissues begin to develop into bone, cartilage, vessels, and meninges. At approximately 50 days of gestation, the nasal and frontal bones develop by intramembranous ossification of the mesoderm.⁷⁹ At these early stages, the nasal and frontal bones remain separated by a space called the fronticus nasofrontalis. The floor of the skull base develops by endochondral bone formation. The nasal capsule, part of the chondrocranium, is a cartilaginous mass that will give rise to the lateral masses of the ethmoid inferior concha and the anterior two-thirds of the midline nasal septum, which remains cartilaginous.

The prenasal space develops between the nasofrontal bones and the nasal capsule. At the end of the second gestational month, a diverticulum of dura extends anteroinferiorly through the prenasal space transiently to reach the superficial ectoderm that will become the skin of the nose. As growth progresses, the nasal process of the frontal bone grows inferiorly to surround dural projections, creating a canal known as the foramen cecum. The foramen cecum eventually fuses with the fronticus nasofrontalis at the area of the future cribriform plates. The dural diverticulum eventually involutes and retracts through the foramen cecum. The most widely accepted theory of nasal sinus tract development implicates a defective or incomplete process of nasofrontal fusion. If the dural projection remains adherent to the skin, a small dimple may be seen at the external orifice of the sinus tract. The sinus can terminate anywhere along the path of the dural projection or even extend through the foramen cecum into the cranium.⁸⁰ Dermoid cysts or tumors can develop as a result of cellular desquamation of the dermal elements lining the tract. Upon histologic examination, the dermoid sinus contains both ectodermal and mesodermal derivatives. It is composed of a stratified squamous epithelial lining with specialized adnexal tissues that may include hair follicles, pilosebaceous glands, and smooth muscle.⁸¹ Intracranial extension of the dermal sinus tracts is most frequently extra-axial, usually attached to the dura or confined within the leaves of the anterior falx. Intra-axial extension into brain parenchyma is less common.

17.3.2 Signs and Symptoms

Cranial dermal sinuses can present at any age, although the majority (84%) are diagnosed in patients younger than 5 years of age. Males and females are affected equally.⁸² There may be no symptoms, or the clinical presentation may include recurrent episodes of meningitis, mass lesions, skin dimples, or a combination thereof.^{80–82} The mass lesions may be superficially located (subcutaneous) or deep-seated (intracranial). Nasal dermal sinus tracts may present as a visible cutaneous opening or dimple and/or an associated nasal mass. Although the lesions are most commonly located along the midline, paramedian locations have been reported. The dermal sinus pit may be anywhere between the nasal columella and the nasion.⁸³ Dermoids at the nasal tip are not uncommon (► Fig. 17.41). Up to one-third of patients can be asymptomatic at the time of diagnosis. Local drainage of uninfected sebaceous debris may be seen, and some patients will present with an infected, swollen, erythematous, and tender tract.⁸⁴ Fine black hairs arising from a midline nasal dimple should alert the clinician to the strong possibility of an underlying sinus tract. Infection of an intracranial or extracranial site or both was found in 43% of all patients in one series, and 51% had an associated mass lesion.¹¹ Patients should be suspected of harboring a dermal sinus tract when they present with recurrent bouts of meningitis of unknown etiology. *Staphylococcus aureus* is the most common cause of recurrent meningitis in these patients.⁸⁴ A careful examination of the entire midline structure should be undertaken, including shaving the hair over the inion. Occipital dermal sinuses commonly present with a dermal pit near the inion, although the dimple may be located over the supratentorial area or as far inferiorly as the upper cervical spine.⁸⁵ Hemangiomatous skin discolorations commonly surround occipital dermal tracts. Occasionally, the

only sign may be a small amount of discharge from an occult dermal pit within the hairline and recurrent bouts of meningitis (► Fig. 17.42).

17.3.3 Diagnostic Studies

Currently, the best method for diagnosing dermal sinus tracts includes a combination of MR imaging and CT.^{86–88} MR imaging, with and without gadolinium, may demonstrate soft tissue intensity in the subcutaneous fat of the nose, representing the tract itself (► Fig. 17.43). Associated dermoid tumors can be visualized and exhibit short T1 and T2 relaxation times. Epidermoids show prolonged T1 and T2 relaxation times compared with brain tissue. CT (bone algorithm) can demonstrate the tract traversing the bony skeleton (► Fig. 17.44). The most important information obtained from these studies is an assessment of the extent of the dermal sinus, and particularly a determination of whether intracranial extension of the sinus or an intracranial cyst is present (► Fig. 17.45). It must be realized, however, that both of these imaging modalities may have pitfalls. The fatty metamorphosis of the marrow and the signal intensities that accompany frontal sinus aeration can misrepresent the findings. These changes occur between 1 and 5 years of age, the same age range at which most patients are most likely to present. Care must be taken not to confuse the crista galli or the subadjacent plate of the ethmoid for a dermoid tumor. The

central portion of these bones begins to undergo fatty changes at approximately 12 months of age. Such misinterpretation may lead to an unnecessary craniotomy. Plain skull films do not yield significant information and are not currently used.

17.3.4 Surgical Treatment

The surgical principle governing the management of any dermal sinus (cranial or spine) is that the tract and any associated dermoid tumors must be prophylactically removed following diagnosis. Furthermore, excision of the tract should include its full extradural and intradural extensions. The goal is to remove these lesions before they become infected or meningitis develops. Simple excision of the sinus tract to the level of the bone is inadequate. Because these tracts are lined with epithelium that can lead to tumor development, an incomplete resection may lead to subsequent meningitic episodes or deep tumor development. If the excision of these lesions is delayed until they become symptomatic (infected), the subsequent management will be more difficult, creating a less than optimal final result. If the patient presents with an infected tract, meningitis, or hydrocephalus, these conditions need to be treated and controlled before surgical resection.

When nasal lesions are treated, a plastic surgeon should be part of the team. Our approach is to perform a single-stage procedure, although some authors advocate staged operations whereby a craniotomy is done first and the nasal component is resected at a later date.⁸⁹ We see no advantage in taking such an approach. Given that nasal tracts originate in the nose and extend through the foramen cecum, a midline partial rhinotomy and a frontal craniotomy may be needed to resect these lesions fully. Intracranial dermoids are removed, the dura closed, and the tract amputated below the level of the bone. The entire tract should be fully removed from the skin and intranasal structures to prevent future recurrence or infection.⁷⁹

17.3.5 Prognosis

Patients with completely resected asymptomatic tracts and dermoid tumors have an excellent prognosis. Incompletely resected tracts place the patient at higher risk for the development of

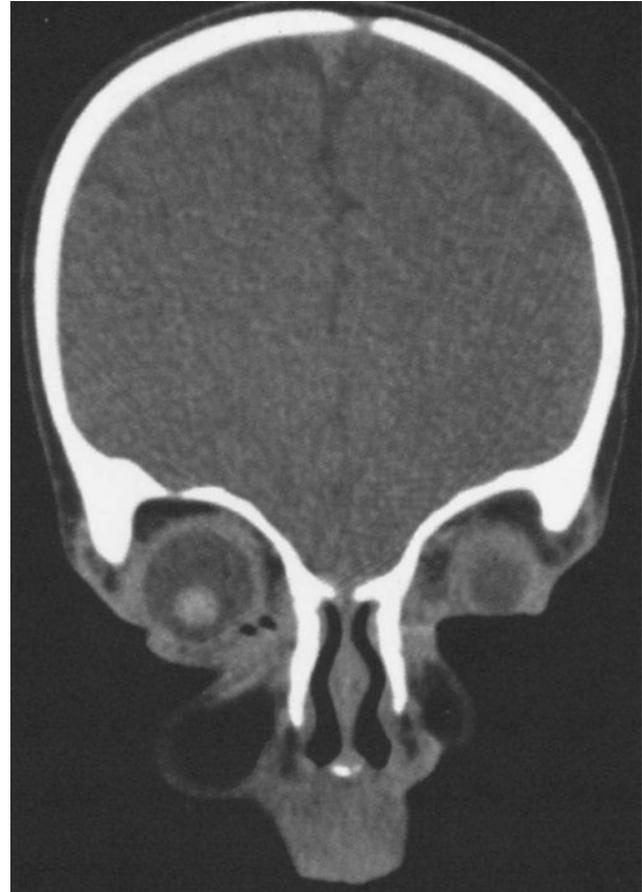

Fig. 17.45 A computed tomographic scan, coronal view, showing the bony canal of a dermal sinus tract anterior to the crista galli and cribriform plate.

meningitis, tract infection, and cystic tumors. Every attempt should be made to achieve gross total resection of these lesions.

Pearls

- If there is evidence of nasolacrimal duct obstruction in a patient with a sincipital encephalocele, the duct should be cannulated with a Silastic tube (Dow Corning, Midland, MI). The tube should be left in place for 6 months to prevent dacryocystitis and reestablish duct patency.
- Patients who have sincipital encephalocele with ventriculomegaly should undergo ventriculoperitoneal shunt placement before encephalocele repair to prevent postoperative CSF leaks.
- Every attempt should be made to preserve “normally functional” brain and occipital encephaloceles. However, most often the tissue is fibrous, gliotic, and nonfunctional and so can be easily amputated.
- Dermal sinus tracts should be excised “prophylactically,” and the tract and associated dermoids should be totally excised to prevent recurrence.
- The use of full-thickness calvarial grafts in young infants provides an excellent method for obtaining complete osseous closure of the bony defects associated with cranial encephaloceles.

18 Congenital Lesions of the Scalp and Skull

Suresh N. Magge, Gary F. Rogers, and Robert F. Keating

Congenital lesions of the skull and scalp are common, and the vast majority of them are benign. Nevertheless, the treatment of these lesions requires a good understanding of their natural history, radiographic findings, diagnostic criteria, and treatment options. Treatment ranges from observation to multidisciplinary care involving multiple specialists. Although we cannot cover all the lesions, we attempt to discuss some of them that are seen commonly in a pediatric neurosurgical practice. In particular, we discuss three commonly encountered entities: aplasia cutis congenita, atretic cephaloceles, and parietal foramina/cranium bifidum.

18.1 Aplasia Cutis Congenita

18.1.1 Background

Aplasia cutis congenita (ACC), also referred to as cutis aplasia, is a heterogeneous condition in which one or more components of the scalp and/or skull are absent at birth. Histologically, cutis aplasia is characterized by a lack of epidermis, dermis, fat, and in severe cases muscle and/or bone (► Fig. 18.1). Although the condition was first described in the extremities by Cordon in 1767,¹ and any part of the body can be affected, 85% of cases involve the scalp.²⁻⁷ ACC of the scalp was first described in 1826 by Campbell,⁸ and Billard later reported a concurrent cranial defect.^{3,8-10} Since that time, there have been hundreds of reports of this condition.³

ACC is reported to occur in about 1 in every 10,000 live births and is more common in females than in males.^{2,11} Nevertheless, ACC is likely underreported because mild cases may be confused with other scalp conditions.² The cranium and dura are affected in about 15% to 30% of cases² (references 5, 6, 8, and 9 in Bharti et al²), and these cases require acute treatment. Dessiccation of the dura, especially over the superior sagittal sinus, can result in significant morbidity or death.

Fig. 18.1 Aplasia cutis congenita in a newborn with full-thickness defect and exposed dura.

18.1.2 Causes

A number of theories have been posited over the years to explain the cause of this condition. The etiology seems to be multifactorial, as no single theory seems to explain ACC fully. As with many conditions, both genetic and environmental factors appear to be related to ACC. Most cases of ACC occur sporadically, but there is a family history in 40% of affected children. The majority of hereditary cases of ACC are passed in an autosomal-dominant fashion,¹²⁻¹⁶ although autosomal-recessive inheritance has also been reported^{13,14,17,18}

Multiple syndromes show association with ACC. One of the best known is Adams-Oliver syndrome. Children with Adams-Oliver syndrome can have ACC, with or without involvement of the skull or dura. In addition, these children may have shortened or absent fingers or toes, loss of the metacarpals, absence of the lower extremities below the calf, and mottling of the skin. Adams-Oliver syndrome is thought to be inherited in an autosomal-dominant pattern.^{2,13,19,20} Other syndromes associated with ACC include Setleis syndrome, Anderson-Hollister-Szalay syndrome, Johanson-Blizzard syndrome, and Goltz syndrome.^{2,5,21,22}

A number of environmental factors have also been cited as possible causes of ACC. According to one theory, amniotic adhesions to the skin of the fetus tear off, leaving areas devoid of skin. This theory seemed to have been disproven, at least in most cases, because most examined cases showed normal placentas.^{3,23}

Teratogens have also been implicated in causing ACC. These include heroin, alcohol, cocaine, methotrexate, antithyroid medications, angiotensin-converting enzyme (ACE) inhibitors, and other medications.^{2,5,6,24} Another possible mechanism is tension on the fetal skin during development. It is thought that tension on the vertex, which sustains the greatest amount of stretch during head growth, can disrupt the skin, leading to ACC.^{2,5,24,25} Other factors that have been proposed as possible mechanisms leading to ACC include vascular disruption of the fetus leading to ischemic injury^{2,4,6,22,24,25}, intrauterine infection, and intrauterine trauma.^{2,6,26} Of note, Ingalls in 1933 found that there was an associated fetus papyraceus, or mummified dead fetus, at the delivery of many newborns with ACC of the trunk or limbs.^{3,27}

As one can see from this myriad of possible causes, there is no unifying theory to explain ACC. Rather, it is thought to be multifactorial in etiology, with both genetic and environmental causes. Different classification schemes have been proposed to describe the disease. Frieden devised a nine-part classification system based on area of the body affected, other abnormalities, and inheritance pattern.³

18.1.3 Pathology

Lesions of ACC do not have the normal histology of stratified squamous epithelium of the scalp. Instead, they show a loose fibrous stroma devoid of hair follicles, epithelium, and sweat glands. They are covered by a thin epithelial membrane with a thickness of one cell layer.^{13,28-30}

18.1.4 Clinical Presentation

The presentation of ACC can vary greatly, and the management of a lesion requires a careful examination and understanding of its extent. More than 80% of lesions are located at or near the midline, and many are situated close to the parietal hair whorl.^{3,13,28,31} These lesions can present in all sizes. Most are less than 2.5 cm in diameter, but some can be more than 8 cm in diameter.^{13,32} Larger lesions, and lesions that involve the skull and dura, can pose significant challenges to treatment.

Many cases of ACC present as a hairless patch of thin skin over the vertex. Small hairless patches can sometimes be confused with conditions other than ACC. ACC affects the skull or dura in about 15 to 30% of cases² (references 5, 6, 8, and 9 in Bharti et al²). Serious morbidity can result if the dura of the superior sagittal sinus is exposed. The exposure of underlying structures can lead to infection, sagittal sinus thrombosis, and/or major hemorrhage from the superior sagittal sinus, which can even lead to death. Hemorrhage can occur if the sinus becomes dry and brittle.² Indeed, one of the cases first described by Campbell was that of an infant who died after bleeding from an exposed superior sagittal sinus.⁸ This rare but known scenario must be recognized by the physician in order to guide treatment and prevent major morbidity (► Fig. 18.2).

18.1.5 Treatment

The treatment of ACC is based on the size and location of the lesions.² Fortunately, most defects are small and relatively superficial. These are effectively managed with local wound care. Large areas with exposed dura can also be safely managed without surgery, but the potential morbidity of these lesions is much greater, and treatment must be monitored carefully.⁶ Conservative treatment requires maintaining a moist environment at all times. Typical dressings include hydrocolloid, petrolatum with or without antibiotic ointment, bacitracin, and silver sulfadiazine. Many authors advocate topical antibiotic ointments to provide both a moist wound-healing environment and, conceptually, prophylaxis against infection and meningitis. If a topical ointment is applied, it should be applied in a thin coat to reduce buildup and reapplied only as needed to main-

tain a moist wound bed. It is important to clean gently any caked or dry emollient from the wound because this layer can create a barrier to the beneficial effects of subsequent medication. Adjuvant treatment with oral or intravenous antibiotics is controversial. There have been reports of adding growth factors (e.g., recombinant human fibroblast growth factor) to the wound to promote further healing, although the need for this is dubious.³³

If larger areas of dura are exposed (> 2 cm²) or circumstances prevent reliable outpatient compliance with dressing (e.g., dysfunctional family dynamics), we strongly recommend hospital admission until the dura is completely covered with granulation tissue. In a neonate, this occurs very rapidly and reduces the likelihood of preventable complications.

Some authors advocate early treatment with allograft and autograft to reduce the scarring associated with spontaneous healing. Apligraf (Novartis, Basel, Switzerland) is a bilayered skin construct formed from allogeneic foreskin keratinocytes and a dermal layer consisting of bovine collagen lattice and human fibroblasts. It has been used but patchy contractures still result, likely from reaction to the bovine component.³⁴ Other skin substitutes, such as those made by Integra (Plainsboro, NJ), have been reported to yield good results.³⁵ The placement of cultured epithelial autografts on the surface of AlloDerm (KCI Lifecell, San Antonio, TX) has also been tried, although the aesthetic outcomes are unknown.³⁶ Coverage with autograft or allograft material may achieve earlier closure of the wounds, but it is unclear if and how these methods can reduce scarring. In our opinion, the lack of evidence to support the superiority of these treatment options over more conservative measures does not justify their relatively high cost.

Although even the largest areas of deficiency will heal if a clean, moist wound environment is maintained, conservative treatment requires constant surveillance and a well-trained and motivated ancillary staff. If this level of care is not available and prolonged observation with local wound care is impractical, one may consider early wound closure to ensure a safer and more predictable outcome, especially if the dura overlying the sagittal sinus is exposed, which can lead to hemorrhage and death. Early closure can be achieved by using various skin substitutes, as noted above, or by rotating local tissue flaps.^{25,37} The

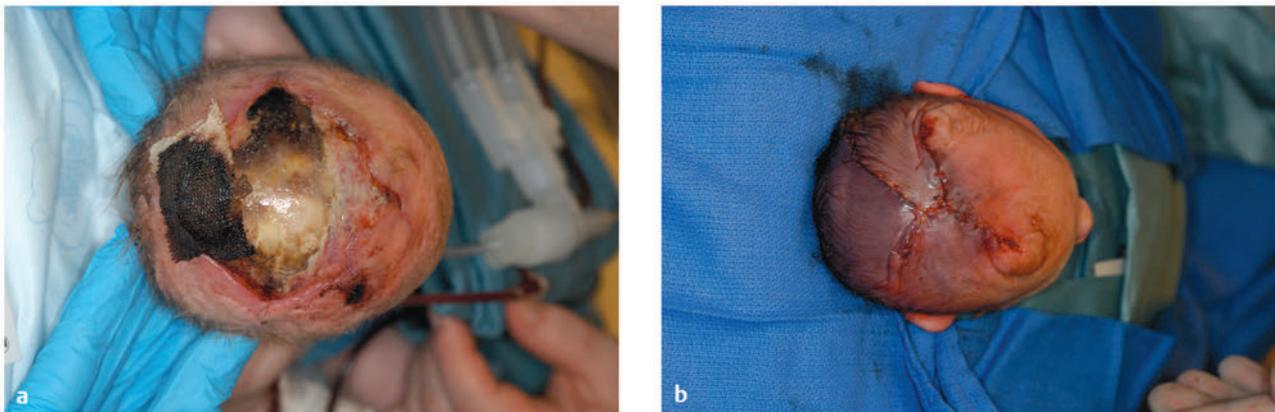

Fig. 18.2 (a) Aplasia cutis congenita with desiccated dura and exposed superior sagittal sinus. This child had a hemorrhage from the superior sagittal sinus shortly after presentation in the intensive care unit and required emergency rotation flap closure. (b) Photograph after closure of defect.

benefit of early closure must be weighed against the potential pitfalls. For example, grafted material can fail to adhere or become infected. Moreover, grafts may be difficult to separate from the underlying dura if later scar excision is planned. Rotational flaps in infants can undergo partial or complete necrosis. Surgical delay should be considered if possible before larger, complex, or multiple-pedicle reconstructions. Some authors have demonstrated good results with the use of composite bone and soft-tissue flaps at a very early age.³⁸

Defects that extend into the deep dermis will leave a scar, and hair will not regrow in these areas. In such instances, many families express an interest in reducing or removing the scar. The timing of this depends on the size of the area of alopecia and whether any underlying bone defect is present. If it is, we recommend deferring any soft-tissue reconstructive procedure until the bone has healed or until the child is at least 2 years of age because little osseous healing can be expected after this time.

The best method of soft-tissue and/or bone reconstruction depends on the size of the defects. Areas of alopecia with a width of up to 2 cm can be addressed with simple excision and closure. Larger areas up to 4 cm in width can also be closed with this method, but more sophisticated techniques are required to mobilize the scalp. Specifically, the scalp must be widely undermined and the galea aggressively scored with multiple releasing incisions. When the ability to close the defect fully is in question, it is advisable to begin with only a single incision along one edge. After mobilization, the tissue excision can be tested by overlapping the edges of the wound and excising the redundant tissue. If the entire scar cannot be excised, the wound is closed, and one can come back in 6 months to a year to complete the excision. This method of serial excision is very effective and can address even very large areas of alopecia. In rare instances in which the area of alopecia is extensive, tissue expansion or rotational flaps should be considered.⁹ The former option requires two procedures and has potential complications, such as infection and expander extrusion or rupture. In very young infants, it also can deform the cranium. The latter option works well if carefully planned. The use of surgical delay is advisable in most instances. Delay involves performing all incisions and elevating, but not rotating or in-setting, the flaps several weeks before the definitive reconstruction. This step significantly improves the perfusion and durability of soft-tissue flaps, especially those with a high length-to-width ratio. It is advisable to seek the help of an experienced reconstructive surgeon before embarking on this treatment path.

Bone defects that are large enough to pose a safety concern (>2 cm²) may warrant grafting. In most cases, the overlying soft tissue is of poor quality, and bony grafting should be done concurrently with the soft-tissue reconstruction to ensure a healthy, vascularized covering for the graft. This can be done with corticocancellous particulate autograft in a younger child or split cranial bone if the child is older.³⁹ We advise against the use of alloplastic materials in pediatric cranial reconstruction because they have higher rates of extrusion and infection than autografts, are very expensive, rarely osseointegrate, and do not grow with the cranium. There are few if any indications for alloplastic cranial reconstruction in the pediatric population.

18.2 Atretic Cephaloceles

18.2.1 Background

Cephaloceles are generally defined as herniations of structures of the cranium through a defect in the skull, and they can have a fairly diverse presentation with associated abnormalities of the brain.^{40,41} Three major types of cephaloceles include encephaloceles, meningoceles, and atretic cephaloceles. These lesions are often defined by their location as either occipital or parietal.⁴² Parietal cephaloceles have been described as having a worse prognosis,⁴² but this has been contradicted elsewhere.⁴¹

Encephaloceles (or meningoencephaloceles) are herniations of the brain and meninges, and children with these malformations often have the worst prognosis for cognitive development. Meningoceleles are herniations of meninges that do not contain cerebral tissue. These lesions are filled with cerebrospinal fluid (CSF) that communicates with the underlying brain via a connection.

Atretic cephaloceles have been described differently by various sources, which can be quite confusing. In general, an atretic cephalocele is a congenital lesion of the scalp and skull consisting of a skin-covered dural sac that may or may not contain fluid. Each lesion generally has a stalk that connects it to the underlying dura. Atretic cephaloceles can be either flat or cystic. We distinguish cystic atretic cephaloceles from meningoceles in that the stalk of an atretic cephalocele usually has a closed lumen, and the cyst fluid does not freely communicate with the underlying brain. On the other hand, meningoceles contain CSF that communicates with the underlying brain.

These lesions can contain rests of glial tissue in addition to meninges.^{41,43} Some may think of the lesions as “burnt-out” or sequestered cephaloceles.⁴⁴ Because they contain neural tissue, they have also been referred to as *heterotopic neural nodules*.⁴⁴ Other authors have used the terms *rudimentary cephaloceles*, *occult cephaloceles*, and *abortive cephaloceles*.^{41–43,45,46}

Atretic cephaloceles have been reported in various studies to comprise 25⁴² to 50%⁴¹ of all cephaloceles.

18.2.2 Causes

Most atretic cephaloceles are thought to be sporadic, but some have been seen in association with underlying genetic syndromes. Walker-Warburg syndrome, or cerebro-ocular dysgenesis–muscular dystrophy syndrome, is a rare autosomal-recessive form of muscular dystrophy.⁴⁷ It is associated with multiple cerebral anomalies, including cephaloceles. A number of other genetic syndromes or familial associations have been described with atretic cephaloceles.^{48–51} In addition, some teratogens have been linked to cephalocele formation.⁴¹

Multiple theories have been proposed to explain the formation of atretic cephaloceles. Some believe that they form when the neural tube fails to close. Others believe that the neural tube closes, then reopens and develops abnormally.⁴¹ Drapkin proposed that atretic cephaloceles form from remnants of the neural crest after faulty migration.⁴³ Yokota et al believed that an atretic cephalocele forms after the involution of a true meningocele in utero.⁴²

18.2.3 Clinical Presentation

Atretic cephaloceles generally present at or near the midline in the parietal or occipital regions, often in the vicinity of the posterior fontanel.⁴³ These lesions can present as a flat bump or as a cystic structure (► Fig. 18.3 and ► Fig. 18.4). They are usually skin-covered, but the skin can be quite thin and may be ulcerated or discolored with a vascular stain.^{41,44} The lesions are often hairless, but a thick ring of hair may surround the lesion, often called the “hair collar” sign.⁵² There is generally an associated bone defect. In one study, the lesions ranged in size from 10 to 35 mm.⁴¹

Various authors have proposed different classifications of these anomalies. Drapkin described how some lesions do not communicate with the underlying cranial cavity, whereas other lesions have fibrous stalks that attach to the dura and extend through a distorted superior sagittal sinus to end in the falx or a deeper location.⁴³ Patients with the latter type of lesion often have a high-riding torcular, upward-coursing straight sinus, and high tentorium.⁴³ Magnetic resonance (MR) imaging can demonstrate these and other venous anomalies and show the vertical positioning of the straight sinus.^{53,54} The association of sinus

pericranii with atretic meningocele has been reported.⁵⁵ A number of underlying cerebral anomalies may be associated with atretic cephaloceles.^{41–43,56} Although the necessity of

(D) Preoperative sagittal T2-weighted magnetic resonance image shows cystic atretic cephalocele with stalk connecting it to the underlying dura.

preoperative MR imaging has been debated, it can be helpful to detect vascular and cerebral anomalies and may help with the prognosis for cognitive development.

18.2.4 Treatment and Outcome

Atretic cephaloceles are often treated with surgical excision. There is no absolute indication to remove these benign lesions, but uncertainty about the long-term biological behavior of ectopic meningeal tissue seems to support excision. An incision is made perpendicular to the edge of the lesion. Based on the orientation of the lesion, we choose the direction of the incision to correspond to the longest axis of the lesion. After dissection through subcutaneous tissue, blunt dissection is performed circumferentially around the base of the dural sac to find the stalk. The stalk is then ligated and cut. One does not need to dissect the dome of the dural sac because it often fuses with the epithelium. A layer of pericranium can be closed over the dural stalk. Any abnormal or redundant skin should be sharply excised in an elliptical fashion. The galea and skin are then closed in layers.

Cognitive outcome depends on whether the child has underlying cerebral anomalies. Martinez-Lage et al reported that 8 of 16 patients with these lesions showed normal development. It is important to note that 5 of their patients also had Walker-Warburg syndrome,⁴¹ and these presumably had a worse prognosis.

18.3 Parietal Foramina and Cranium Bifidum

18.3.1 Parietal Foramina

A number of calvarial variations are encountered in a typical practice setting (see box “Examples of Morphological Calvarial Variations (p.234)”). The clinical significance of parietal foramina continues to plague parents and the medical community. It is believed to result from a genetic mutation (*MSX2*, *ALX4*) transmitted in autosomal-dominant fashion⁵⁷ and is estimated to occur in fewer than 1 in 25,000 individuals; many familial examples have been reported in the literature.⁵⁸ An association with Saethre–Chotzen syndrome has also been reported in multiple families.^{59,60}

Examples of Morphological Calvarial Variations

- Parietal foramina
- Cranium bifidum (anterior/posterior)
- Supraorbital notch
- Persistent frontal foramen
- Metopic ridging
- Inca bone
- Occipital foramen

Presenting as symmetric calvarial defects on either side of the sagittal suture, parietal foramina are located close to the confluence of the sagittal and lambdoid sutures. The hallmark indicators of smooth, nonsclerotic defects encompassing both tables

of the skull are a direct result of incomplete ossification around the parietal notch, which is normally closed by the fifth month of fetal development. Although generally present at birth, they are not uncommonly discovered at a later stage. Occasionally, they may be associated with meningeal, cortical, and vascular malformations of the posterior fossa, in addition to epilepsy. Fortunately, the defects are relatively small, often less than 2 cm in diameter, and rarely require any surgical correction. With larger defects, associated emissary veins may be present, so that caution is required if surgical repair becomes necessary. The risk for injury after head trauma has been proposed, particularly in light of cases of skull fractures running through preexisting parietal foramina.⁶¹

For larger defects requiring cranial reconstruction, the use of autologous material is best in the long run. Multiple authors have outlined various approaches to this persistent defect but generally recommend autologous constructs, although mesh plating systems as well as hydroxyapatite have been used.^{62,63} Another approach, recently introduced by Rogers et al, involves the use of an exchange cranioplasty in which full-thickness, healthy bone is transferred from an adjacent area to fill the defect.⁶⁴ Particulate outer or inner table bone is used in a fibrin glue (Tisseel; Baxter, Deerfield, IL) suspension. This has been found to offer excellent regrowth potential and avoid difficulties with a dysfunctional osteogenic dural matrix.

18.3.2 Cranium Bifidum

Cranium bifidum, often thought to represent a persistent posterior fontanel, is a midline variant of the bilateral parietal foramina. It has been hypothesized that cranium bifidum and parietal foramina are the same entity, differentiated only by the age at which they manifest.⁶⁵ Cranium bifidum is differentiated by its more anterior location over the vertex, anterior to the intersection of the lambdoid and sagittal sutures.

Although the majority of defects are located posteriorly, the presence of an anterior cranium bifidum is a common component of frontonasal dysplasia and more often requires surgical correction because of its size and location. Examples of intracranial dermoids becoming infected in association with an anteriorly located cranium bifidum have been described; these required surgical dissociation of the nasal compartment from the intracranial contents.⁶⁶ A more classically located cranium bifidum in the posterior calvaria may herald underlying anatomical variations in the posterior fossa, including atypically placed venous sinuses.⁶⁷ Although the majority of cases of cranium bifidum occur in association with other congenital anomalies, including cutaneous dysmorphology, one can also see isolated calvarial defects without associated abnormalities.⁶⁸

18.4 Conclusion

Congenital lesions of the skull and scalp are common and often benign lesions. Treatment ranges from observation to surgical correction with a multidisciplinary team. The conditions discussed in this chapter—ACC, atretic cephaloceles, and parietal foramina/cranium bifidum—are seen in a typical pediatric

neurosurgical practice. Caring for patients with these conditions requires a good understanding of their pathophysiology and the treatment options available.

Pearls

- The treatment of cutis aplasia depends on the size and extent of the defect.
- Many cutis aplasia lesions can be treated conservatively with moist dressings, although they must be watched very closely. If the superior sagittal sinus is exposed, care must be taken to make sure that it does not dry out in order to avoid serious hemorrhage.
- Atretic cephaloceles are often treated with surgical excision.

19 Craniosynostosis

Lissa C. Baird and Mark R. Proctor

Craniosynostosis is the premature closure of one or more sutures of the cranial vault. Early fusion of cranial sutures will generally cause abnormal growth of the cranial vault and skull base, and it may affect brain growth and development.

Physicians as far back as Hippocrates and Galen recognized the relationship of the cranial sutures to skull deformities.¹ By the 16th century, anatomists had described a wide range of cranial deformities associated with premature closure of cranial sutures.¹⁻⁴ Andreas Vesalius, in his work *De Humani Corporis Fabrica*, illustrated both absent sutures and several abnormal skull shapes, which he described in terms of prominences² (► Fig. 19.1). In 1791, von Sommerring was the first to describe bone growth in the skull as occurring primarily at suture lines, and to note that an abnormal head shape would expand in a plane parallel to a fused suture.⁵ In 1851, Virchow first described characteristic abnormal growth patterns with specific synostoses, and he classified the morphological descriptions still used today.⁶ The premise that normal skull growth tends to be in a plane perpendicular to the suture and abnormal growth is parallel to the fused suture is generally called Virchow's law.

As our understanding has progressed, it appears that the relationship between sutures and skull growth is not as straightforward and linear as originally proposed. Moss, in 1959, was the first to appreciate the deterministic effect of the skull base on the cranial vault and proposed that the primary mechanisms driving cranial deformity originated at the cranial base, not the sutures.⁷ He noted that removal of a fused suture did not always alter abnormal skull growth, an observation that contributed to the development of more complex surgical procedures than simple strip craniectomies.

As a result of better understanding of the condition and newer technologies, the surgical treatment for craniosynostosis has

undergone interesting trends. Early suturectomies in the late 19th and early 20th centuries were abandoned because of poor patient selection and a high mortality rate.⁸ In the mid-1900s, suturectomies were again popularized, but outcomes were variable and limited by early refusion and inconsistent results.^{1,9} The theories of Moss, combined with the pioneering work of Tessier in the 1970s, led to extensive cranial vault reconstruction procedures to correct synostosis that remain popular today. However, with new minimally invasive techniques and adjuvant therapies, such as helmets, springs, and internal distractors, a new era of treatment options is emerging.

19.1 Epidemiology and Etiology

Craniosynostosis affects 1 in every 2,000 to 2,500 live births.^{10, 11} Single-suture synostoses are most frequently observed, with an increased frequency seen in children who have non-Hispanic white mothers.^{12,13} The sagittal suture is most commonly involved, accounting for 53 to 60% of all cases of craniosynostosis with a male-to-female ratio of 2:1. Coronal synostosis follows, accounting for 17 to 29% of cases and manifesting twice as frequently with unilateral involvement as with bilateral involvement. Metopic synostosis occurs in 4 to 10% of cases, and lambdoid synostosis is the least common, accounting for fewer than 2% of cases.^{10,14,15} Syndromic craniosynostosis, representing fewer than 5% of all cases, is discussed in a separate chapter.

The etiology of nonsyndromic craniosynostosis is incompletely understood, and most cases appear to be sporadic.¹⁶ Numerous factors have been implicated, ranging from genetic mutations and metabolic and hematologic syndromes to teratogens such as valproic acid and retinoic acid. Maternal smoking and advanced paternal age have also been implicated.¹⁷⁻²⁰ It is likely that a combination of genetic factors and external forces mediates the pathway to suture fusion. More than 100 mutations have been identified in association with craniosynostosis, including mutations of the *FGFR1-3*, *NELL1*, *MSX2*, *TWIST*, and *GLI3* genes.^{11,21} It is unknown how significant a role these genetic anomalies play in the development of synostosis, and genetic and molecular findings have had only minimal clinical impact thus far on the treatment of patients with this problem.

19.2 Physiology and Anatomy

The skull base and cranial vault originate from neural crest cells that surround the enlarging brain. At 5 to 6 weeks of gestation, dural condensations form, and islands of cartilage subsequently develop over the dura. These islands go on to become the osteoblastic ossification centers that form the calvarial bones. The junction of osteogenic fronts forms sutures, best described as sites of bony adaptation rather than as primary growth centers,²² by 16 weeks of gestation. The mechanistic forces that modulate bone growth at the sutures include underlying brain growth, interactions at the dural-calvarial interface, and external mechanical forces.²³⁻²⁵ Supporting a genetic underpinning to the condition, experimental studies have shown that

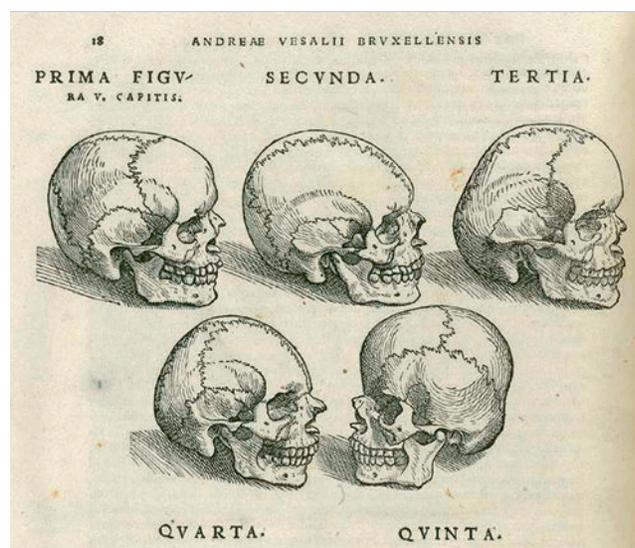

Fig. 19.1 Illustrations of abnormal skull shapes by Andreas Vesalius from *De Humani Corporis Fabrica*. (Courtesy of Oregon Health & Science University.)

compression of a suture, as with an external mechanical force, will cause bone resorption along the suture margin rather than suture fusion.^{26,27} Distraction of a suture, such as with elevated intracranial pressure (ICP), will lead to bone growth along the suture edge, with ensuing enlargement of the calvarial bones and cranial vault. After birth, the cranial vault grows most rapidly during the first year of life, with brain volume doubling during the first 6 months and again by age 2 years. The calvaria then continues to grow in a linear fashion until the age of 6 to 7 years, when growth via sutures is essentially complete.

Virchow's initial hypothesis of skull deformity can be extrapolated to explain the characteristic skull shapes associated with individual forms of craniosynostosis. Delashaw et al redefined the mechanism with the following tenets: two cranial bones connected by a prematurely fused suture will act as a single bone plate, with reduced growth along the margins of that plate, and compensatory skull growth will occur symmetrically along sutures that are in line with a synostotic suture²⁸ (► Fig. 19.2).

19.3 Diagnosis

The diagnosis, management, and treatment of patients with craniosynostosis can be quite variable, depending on the number of sutures involved and the severity of disease. For severe cases or those with syndromic associations like syndactyly, the

initial diagnosis may be established in utero based on morphology. Nonsyndromic craniosynostosis will typically be diagnosed postnatally by observation of a characteristic skull shape. The deformity is generally visible at birth, although occasional mild deformities may be missed. Although the most apparent findings on physical examination will be characteristic calvarial shapes, perisutural ridging may also be noticed. Associated medical conditions, although uncommon in single-suture synostosis, may include midface hypoplasia, deafness, blindness, learning disabilities, speech impairments, swallowing dysfunction, nasopharyngeal airway obstruction, heart and lung abnormalities, and extremity abnormalities.

Radiographic imaging may be used to corroborate the physical examination findings or to rule out an associated intracranial abnormality, although it is rarely needed to establish the diagnosis. It is important to define clearly the questions to be addressed by any imaging and avoid unnecessary studies. Underlying intracranial pathology may be present in a significant number of patients with craniosynostosis,²⁹ although it is not likely to have a major impact on treatment strategies.³⁰

Skull X-rays are frequently obtained when a diagnosis of craniosynostosis is suspected, yet they have minimal diagnostic value beyond that of a detailed physical examination and are often misinterpreted. Three-dimensional computed tomography (CT) provides a comprehensive view of the suture as well as the overall head shape (► Fig. 19.3a,b) and will clearly con-

firm a diagnosis of craniosynostosis, although it should be used judiciously. Exposure to CT has been associated with subsequent malignancies,^{31,32} and all effort should be made to minimize the unnecessary exposure of infants to radiation. Sedation risks will also be added to the potential negative factors associated with neuroimaging. Three-dimensional CT should be reserved for those cases that require visualization of the skull base, involve multiple or complicated suture pathology, or have an unclear diagnosis. If the diagnosis of synostosis is clinically obvious and concern for brain pathology exists, the use of ultrasound or magnetic resonance (MR) imaging should be considered a safer alternative to CT.

19.4 Indications for Surgical Treatment

There is wide variation in the management of craniosynostosis. No definitive data exist to guide optimal timing or type of surgical intervention, and treatment will vary based on age of the patient at presentation, location and number of synostoses, severity of deformity, and ultimately the preferences of the treating surgeon(s). In order to standardize the care of these children, the Centers for Disease Control and Prevention (CDC) brought together international specialists in all associated disciplines to establish and publish parameters of care.^{11,33} Common themes of that document include the complexity of the management of these children and the benefits of multidisciplinary care in craniofacial centers.

The two main indications for the surgical treatment of craniosynostosis are to correct the skull shape for aesthetic and psychosocial considerations and to make certain that there is adequate space for normal brain growth. From an aesthetic perspective, the deformities associated with craniosynostosis are generally progressive for the first year of life, and their social and psychological impact on affected children is in itself sufficiently concerning to justify treatment.³⁴

The relationship between craniosynostosis and brain development is not completely understood. It has been postulated that global intracranial hypertension,^{35–39} focal brain hypoperfusion,^{40–42} and mechanical deformation of neuroanatomical structures^{43–47} may all play varying roles. Studies attempting to demonstrate a relationship between intellectual and behavioral

disabilities and craniosynostosis have had varying and sometimes contradictory results.^{14,46–66} Some data have suggested a benefit to early surgical treatment; however, recent genetic studies have suggested that some genes implicated in craniosynostosis are also essential to brain growth,⁶⁷ and it remains unclear if skull morphology is simply associated with or an influential factor in abnormal brain development.

A study assessing the neurodevelopment of infants both before and after surgical treatment for single-suture craniosynostosis found that developmental testing results were similar after surgical treatment and within a normal range when compared with those of controls.⁶⁴ Surgical timing did not appear to affect patient scores. Although it appears that developmental scores remain generally normal and stable in the perioperative periods, differences become more apparent later in childhood. A recent multicenter study demonstrated consistently lower mean neurodevelopmental scores in 3-year-old children who had been treated for single-suture craniosynostosis when they were compared with controls,⁶⁸ suggesting that these children are at risk for developing cognitive and behavioral disabilities in their school years, regardless of surgical correction.

Although the risk varies depending on the specific diagnosis, a small but significant percentage (4 to 14%) of patients with single-suture synostosis may develop intracranial hypertension,^{35,69,70} and the incidence is as high as 47 to 67% in patients with multiple involved sutures.^{35,69,71} The underlying pathologic mechanism responsible for elevated ICP is likely multifactorial but may include cephalocranial disproportion, venous outflow obstruction, upper airway obstruction, hydrocephalus, and narrowing of the cranial foramina.^{35,70,72–74} Intracranial hypertension may develop gradually, but it should be evident within the first 6 years of life, when brain growth is nearly complete.

The relationship of elevated ICP to cognitive outcomes is unclear. Renier et al performed psychometric testing and invasive ICP monitoring in children with craniosynostosis in a 1989 report from the Hôpital des Enfants Malades in Paris.⁶⁹ Elevated ICP (> 15 mm Hg) was found in 8% of patients with sagittal synostosis, 6% of those with metopic synostosis, and 12% of those with unilateral coronal synostosis. Patients who had multiple fused sutures or who presented after 1 year of age had higher rates of pathologically elevated ICP. A statistically significant relationship was found between ICP and cognitive capacity, with higher ICPs correlated to lower developmental quotients (DQs) and intelligence quotients (IQs). Other relevant reports in the literature have demonstrated improved behavior with resolution of papilledema,^{75,76} improved IQ and developmental progress following cranial vault expansion for documented intracranial hypertension,⁶⁹ and poorer cognitive function in those children with elevated ICP presenting after the age of 3 years.⁶⁹

19.5 Surgical Treatment

Surgical methods for correcting craniosynostosis-related skull deformities have evolved over time, and multiple techniques have been found to have acceptable results. Available data have yet to demonstrate a single best procedure for the treatment of synostosis, which would indicate that there are many acceptable methods for treating the condition. Treatment considera-

tions should include patient age, severity of the disorder, and associated medical conditions. Intervention early in life has the advantage of utilizing the effects of the rapidly growing brain to reshape the skull, along with halting secondary deformities in the face, skull base, or cranial vault that occur over the first year of life. Generally, the procedures in young infants tend to be less invasive, but the increased surgical risk in smaller infants should be considered. Endoscopic techniques in which postoperative helmets are used to direct skull growth are generally best performed by 3 to 6 months of age, whereas spring- or distractor-mediated techniques can be used in older infants, as brain growth is no longer the driver of skull growth. Open cranial vault remodeling procedures are often delayed until 6 to 12 months because they are associated with greater blood loss and longer operative times, and many surgeons have observed an increased incidence of revision surgery in patients operated on before 6 months. Treatment options become more limited as a child grows older, and therefore early diagnosis and referral to a craniofacial center are important.

19.5.1 Open Reconstructions

In the 1970s, Tessier pioneered the technique that remains the standard of care to this day.^{77,78} Extensive surgical reconstruction was performed during which large segments of cranium were removed, remodeled, and stabilized with rigid fixation. This procedure had the advantages of establishing the desired skull shape and size intraoperatively, and of achieving predictable immediate outcomes. Disadvantages to these open procedures include significant blood loss, lengthy surgical times and hospital stays, and frequent need for postoperative intensive care unit monitoring. Because surgery is usually delayed until the patient is older in order to minimize operative morbidity, the cranial deformities can become more severe before intervention. The manipulation of large segments of the skull also disrupts the dural-calvarial interface, which may affect future growth and lead to less predictable results over time.

19.5.2 Minimally Invasive and Endoscopic Surgery

Endoscopic and minimally invasive treatments for craniosynostosis are growing in both popularity and demand by patients' families. Although early suture release surgeries failed to correct cranial deformities in a substantial percentage of patients because of rapid sutural refusion, external orthoses, internal springs, and distractors have negated this problem. Barone and Jimenez published their initial experience with endoscopic suturectomy and adjunctive postoperative orthotic treatment in 1999,⁷⁹ and their data have been supported by others.⁸⁰⁻⁸² In comparison with conventional open cranial vault remodeling, there are significant reductions in blood loss and need for transfusions, smaller incisions, shorter surgical times, shorter hospital stays, and overall decreased hospital costs. The smaller operations are more limited in spectrum, however, and older patients or those with severe cranial deformities may not be candidates.

The benefit of shorter operative times in these procedures may be profound; a recent report from Naumann et al demonstrated lower mean neurodevelopmental scores among children who had undergone lengthier operations and had greater exposure to inhaled anesthetics for cranial vault surgery for single-suture craniosynostosis during infancy.⁸³

Postoperative skull-molding helmets are most commonly used as an adjunct to endoscopic strip craniectomies. Helmets have the advantage of being adjustable over time, and they have the capacity to modify skull growth in three dimensions. However, they are less effective in infants older than 3 to 6 months. Springs and distractors have the disadvantage of requiring an additional operation to remove them, but they allow predictable advancements in a single plane of growth and also can be used in older children because brain growth is no longer the essential driver of skull growth.

Regardless of surgical techniques, long-term follow-up is important in children treated for craniosynostosis; it should include observation of cranial vault growth and morphology as well as of neurocognitive and psychosocial development until at least 6 years of age.^{11,33} Perhaps the most useful tool for following a child with craniosynostosis is head circumference. If the growth rate falls, deformity recurs, or clinical symptoms ensue, the child should be evaluated with appropriate imaging studies and an ophthalmologic evaluation. Adjunct procedures may be necessary in a subpopulation of these patients, regardless of the type of initial treatment.

19.5.3 Surgical Techniques

The technique for surgical reconstruction should be tailored to the type of synostosis and the age of the patient, and each surgeon will develop certain nuances in the way the procedures are performed. Interestingly, despite the relatively wide variations in phenotypic presentations, the surgical approaches have many similarities. It would be beyond the scope of this chapter to describe each technique for each type of synostosis in great detail, as authors have described literally dozens of variations for each suture type. However, there are many broad concepts that are important for both minimally invasive and open techniques that are discussed here, with the salient features for particular sutures covered in the individual sections that follow.

Endoscopic Techniques

Like that of open suturectomy in the past, the main goal of minimally invasive techniques is to release the fused suture (s) without an attempt at major reconstruction or contour change at the time of surgery. This is especially true for metopic, coronal, and lambdoid sutures and also can hold true for sagittal synostosis, although some authors recommend fairly wide vertex craniectomy and parietal barrel staving for this condition. The incisions are generally limited to 2 cm, and it is important to avoid wide dissection of the soft tissues so as to avoid unnecessary bleeding. Bur holes are placed with a high-speed drill and then locally enlarged with a Kerrison rongeur. Once this is achieved, the periosteum is stripped from the outer surface of the bone, and the endoscope is used to strip the dura from the undersurface of the fused suture. The surgery is made particularly feasible by the

ease with which dura separates from a fused suture. Finally, the craniectomy may be completed with heavy scissors, ultrasonic bone aspirators, or a high-speed drill. Bone edges can then be coated with wax or Gelfoam, with a pressure dressing placed after wound closure for several hours. Despite concerns about the risks for uncontrolled bleeding from torn venous sinuses, the experience of multiple authors has clearly shown this to be a safe technique with a much lower risk for bleeding than open operations.^{79,80,82,84} Within 1 week of the procedure, the infant is fitted with a cranial molding helmet. An orthotist and the craniofacial team follow the patient closely and make necessary adjustments to the helmet until the desired phenotype is achieved or the infant reaches 1 year of age.

Open Cranial Vault Reconstruction

These operations, pioneered by Tessier in the 1970s, are by and large variations of similar procedures. Indeed, metopic and coronal suture operations are very similar variations of what is commonly referred to as the fronto-orbital advancement. The patient is placed supine—except in the case of some types of sagittal synostosis, when a more posterior correction is anticipated—with the head stabilized in a horse-shoe headrest. In all cases, the cranium is accessed via a bicoronal skin incision, which gives excellent access to any portion of the skull and is more cosmetically acceptable than a bifrontal incision. A zigzag incision is used in order to minimize the visibility of incisional scalp alopecia. Minimal hair shave tends to be necessary. Incisions in the anteroposterior plane, occasionally used for sagittal synostosis, are very difficult to work with if revision surgery is ever needed. The anterior and posterior scalp flaps are dissected in the subperiosteal plane to prevent anchoring of bone to periosteal tissue. The dissection is carried forward into the subperiosteal plane in order to allow bilateral orbital rim osteotomies. Once the skull is accessed, all cranial vault surgeries require the removal of large sections of bone to be replaced in a more anatomically normal position, either homotopically (bone replaced to a similar location) or heterotopically (segments of bone moved to different parts of the skull), based on the surgeon's preference. Bone is removed with high-speed drills, and the rate of dural tears should be low because of the integrity of the dura in children. Sagittal saws and osteotomes are useful for removal of the orbital bandeau, which requires cuts through the frontozygomatic process, roof of the orbits, and nasofrontal junction. Blood loss is often steady, but hemostasis should be achieved with the selective coagulation of emissary veins and the application of wax on bone edges. The advent of absorbable plates truly has simplified the surgery by making secure bone replacement readily achievable. Most commercially available plates resorb in 1 to 2 years. Titanium plates should not be used in infants, as they will migrate intracranially as the skull grows.^{85,86} Once all bone is secured, it is advisable to fill bone gaps with the patient's own bone, often a particulate mixture taken from the inner cortical surface, as gaps often will not fill on their own.^{87,88} The incision is then closed with a subgaleal drain, and pressure wrap head dressing is applied. The specifics by suture site are discussed below.

Metopic Synostosis

Clinical Features

Metopic synostosis leads to a characteristic triangular skull morphology known as trigonocephaly. Severe cases will demonstrate ridging of the metopic suture (“keel” forehead), posterior displacement of the superolateral orbital rims, hypotelorism, flattening of the frontal bones, anterior displacement of the coronal sutures, compensatory bulging of the parieto-occipital region, and temporal narrowing. Normal closure of the metopic suture occurs by 9 months, although physiologic closure can occur as early as 3 months, and not all children with premature closure will develop trigonocephaly. Patients who present with only mild ridging of the suture are best treated with conservative measures only. Trigonocephaly has the highest rate of associated cognitive impairment among the single-suture synostoses.

Open Surgical Techniques

As described above, fronto-orbital advancement is used to normalize the forehead and remodel the supraorbital rim. A bifrontal craniotomy is performed with the posterior extent to the coronal suture. The orbital bar is removed in one piece and reconstructed into a more convex configuration with a midline osteotomy if necessary. To correct hypotelorism, the orbital bandeau can be widened with insertion of a bone strut between the two halves. The reshaped orbital rim is then fixed to the nasal bone and angled forward at the frontozygomatic suture.

The frontal bones are split along the midline and replaced in a widened fashion, with radial barrel staves used as needed to widen it. The remaining temporal parietal region should be barrel-staved and fractured laterally to flare out and match the newly replaced frontal bones.

Endoscopic Techniques

Infants younger than 6 months with trigonocephaly may be considered for an endoscopic strip craniectomy. In general, the results are quite good, although the ultimate frontal bone projection often falls slightly short of that achieved with the traditional fronto-orbital advancement.⁸⁰ For a metopic procedure, the patient is placed supine with the head stabilized on a horse-shoe headrest. One midline incision approximately 1.5 to 2.5 cm in length is made just posterior to the hairline, with an orientation perpendicular to the metopic suture (► Fig. 19.4). Often, two emissary veins will be encountered when the dura is stripped, but these are easily coagulated with bipolar cautery and divided. After the craniectomy, the ultrasonic bone aspirator is helpful in reaching around the frontal curvature to ensure that sufficient bone is removed at the nasofrontal juncture.

Outcome

The long-term outcome with open reconstruction is excellent in more than 90% of patients with nonsyndromic metopic synostosis.^{89–94} Should new metopic ridging or progressive frontal towering occur, additional surgery may be required, but rates for this are very low.⁹⁵ Endoscopic outcomes are also excellent, with effective treatment of the midline ridge and gradual

Fig. 19.4 Positioning of a child for endoscopic release of metopic synostosis.

improvement of the paramidline ridges.^{80,96} The correction of superolateral orbital rim retrusion is often not as significant as what can be achieved with an open procedure, but family satisfaction is very high.

Unilateral Coronal Synostosis

Clinical Features

Unilateral coronal synostosis manifests as anterior plagiocephaly. It has several characteristic deformities, including a flattened ipsilateral frontal bone with compensatory overgrowth at the contralateral orbit. Other ipsilateral findings include a palpable perisutural ridge, bulging of the ipsilateral squamous temporal bone, anterior displacement of the ear in comparison with the contralateral ear, shortening of the ipsilateral anterior cranial fossa, narrowing of the ipsilateral mediolateral orbital dimension, and the harlequin deformity. The harlequin deformity is pathognomonic for coronal synostosis and is seen on radiographs because of the elevation of the sphenoid wing. Bulging of the contralateral frontal and parietal bones can be seen. The nasal radix will be deviated toward the side of the synostosis (► Fig. 19.3 and ► Fig. 19.5).

Strabismus is a common associated finding and can be found in 50 to 60% of patients with coronal synostosis.^{97,98} The shortening of the anterior skull base results in a posteri-

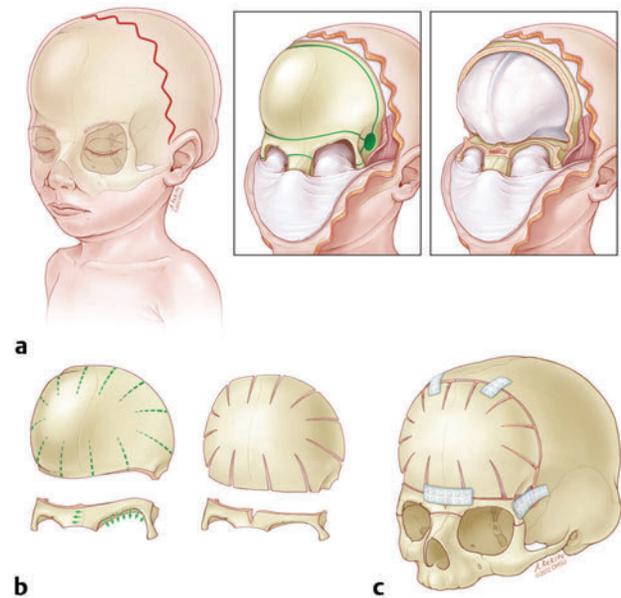

Fig. 19.5 Surgical repair of unilateral coronal synostosis by fronto-orbital advancement. (a) Bicoronal zigzag incision, subperiosteal scalp elevation, and bifrontal craniotomy are performed. (c) The contoured bifrontal bone flap and orbital bandeau are secured with absorbable plates.

orly displaced orbital roof and trochlea, which leads to imbalance at the superior oblique muscle, thus compromising its function. Although surgical correction of the cranial deformity occasionally improves the strabismus, ophthalmologic surgery is frequently needed to address this issue definitively.

Open Operative Technique

Bifronto-orbital advancement with advancement of the ipsilateral orbit is undertaken to achieve orbital normalization and the cosmetic correction of deformity (► Fig. 19.5). The general technique is described above. It is often difficult to create good long-term symmetry in these cases, and because of irregular growth over time, hypercorrection is often performed. Whereas the goal is to create orbital rim symmetry, the affected side is often advanced several millimeters in comparison with the normal side. The deviated nasal radix can also be corrected; it often does not effectively correct over time if not addressed at surgery.

Endoscopic Technique

Severe asymmetry in cases of unilateral coronal synostosis is best treated endoscopically when the patient is younger than 3 months. One 1.5- to 2.5-cm incision is made at the midsuture region in a perpendicular orientation to the coronal suture. The remainder of the technique is identical to that described above, with bone removal from anterior fontanel to the lateral canthus, and patients are similarly fitted with a cranial molding helmet in the first postoperative week.

Outcome

The majority of patients who undergo bilateral fronto-orbital advancement for unilateral coronal synostosis demonstrate an initial significant improvement in cranial shape and have excellent long-term outcomes.^{99–101}

Endoscopic treatment of unilateral coronal synostosis yields excellent outcomes, especially in regard to the nasal root deviation, facial asymmetry, and orbital dystopia.^{80,96} A trend toward a reduction in associated ophthalmologic findings was observed in a recent series published from our institution.¹⁰² Forehead symmetry was significantly improved. Although early results show that fronto-orbital advancement yields slightly better forehead symmetry, the growth patterns after endoscopy appear more normalized over time. Comparison of endoscopic and open techniques with three-dimensional photogrammetry demonstrated statistically significant improvement in facial symmetry in the endoscopic group.⁸⁰

Bilateral Coronal Synostosis

Clinical Features

Bilateral coronal synostosis manifests as brachycephaly with a widened biparietal diameter and frontal towering (turricephaly). Ridging of the coronal sutures is noted, along with flattening of the caudal frontal bone, recessed supraorbital ridges, and bulging of the cephalic frontal bones. The occiput is flattened, and the temporal squamous bones are protruded. Bilateral harlequin deformities can be seen radiographically, and the anterior cranial fossa is shortened bilaterally.

Open Operative Technique

Bilateral coronal synostosis is associated with abnormalities in both the anterior and posterior regions of the skull, and the surgeon must decide if both need to be addressed. For patients with nonsyndromic coronal synostosis, the occipital region is generally not problematic, and the general approach is a fronto-orbital advancement. If attention will be paid to the occipital regions, precautions should be taken, because these children can have issues with stability of the cervical spine or a Chiari malformation.

Techniques for the fronto-orbital advancement are really identical to those described above, with the major goal being advancement of the orbit and frontal bones about 1 cm anterior to the globes. Correction of turricephaly can be difficult and reduction of height can place patient at risk for ICP issues, so this should be done only by surgeons with experience in these procedures.

Endoscopic Technique

The surgical approach to the bilateral endoscopic release of coronal synostosis is simply to perform the unilateral operation on both sides. Early surgery seems to obtain good correction of turribrachycephaly and avoids the secondary turricephaly that ensues over the first year of life in patients whose condition remains uncorrected. Forehead projection is subjectively less

dramatic than with traditional fronto-orbital advancement, in our experience.⁸⁰

Outcome

Initial significant improvement is generally observed in these children after open procedures and endoscopic procedures; however, second surgeries are more common in this group, likely because of the frequent syndromic association.^{103–105} Subsequent development of elevated ICP has also been observed in this population, and patients should be monitored closely for this reason.

Sagittal Synostosis

Clinical Features

Sagittal synostosis is the most common single-suture craniosynostosis. It manifests with a narrow, elongated skull shape known as scaphocephaly (or dolichocephaly). Patients with sagittal synostosis should be screened for signs of intracranial hypertension, especially those who present in later childhood. The degree of deformity should not be reassuring because it does not seem to correspond to the risk for elevated ICP. The region of the suture with the greatest premature fusion will determine whether frontal or occipital bossing, or a combination of the two, is present. Sagittal synostosis is also characterized by perisutural ridging, premature or occasionally delayed closure of the anterior fontanel, and biparietal narrowing.

Open Operative Technique

There are as many open techniques for this procedure as there are surgeons doing the operation. The basic tenets should be to increase the width of the skull and leave the length relatively neutral so as to avoid decreasing the intracranial volume. The surgeon needs to decide if the deformity should be addressed mostly anteriorly, mostly posteriorly, or both anteriorly and posteriorly. The orbital ridge does not require exposure because no significant orbital anomalies are typically seen in sagittal synostosis.

Endoscopic Technique

More than for any other suture, endoscopic treatment of sagittal synostosis has proved to be very effective and is becoming the treatment of choice at many institutions. Patients are positioned prone in a specialized headrest (DORO Horseshoe Headrest; pro med instruments [PMI], Freiberg, Germany) that keeps the head extended (► Fig. 19.6). The torso rests on chest rolls. Two 1.5- to 2.5-cm incisions are made perpendicular to the sagittal suture in the midline. One is placed just posterior to the coronal suture and the other just anterior to the junction of the lambdoid sutures. The subsequent technique is identical to that described above. A cranial molding helmet is fitted during the first postoperative week.

Outcome

Almost all surgical techniques for treating sagittal synostosis report acceptable cosmetic outcomes; however, comparing

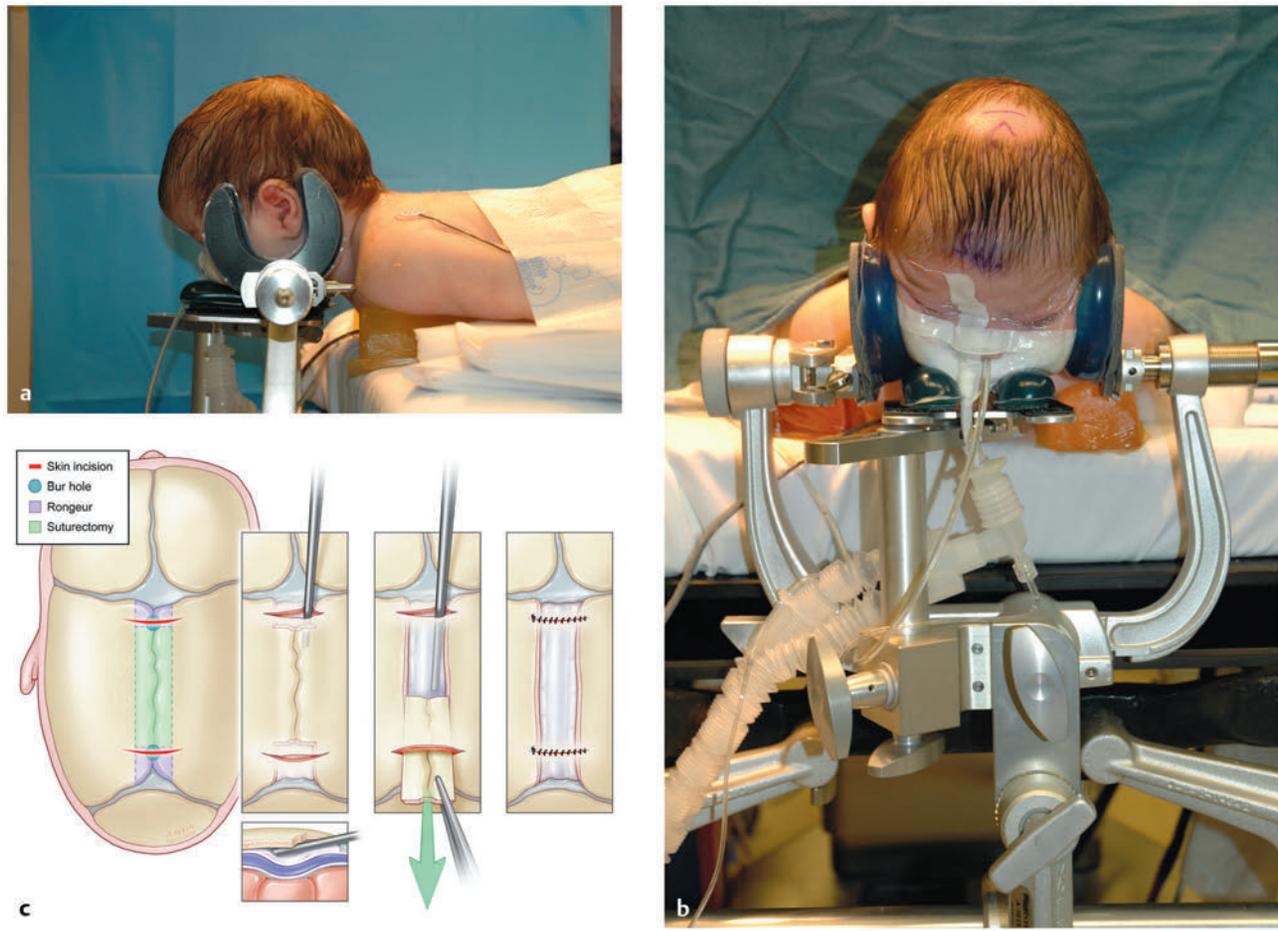

Fig. 19.6 (a,b) Positioning and (c) surgical technique for endoscopic removal of a sagittal suture.

these techniques is difficult without available prospective or long-term data.^{29,106–109} Endoscopic outcomes for sagittal synostosis demonstrate excellent cosmetic correction.^{79,80,82,84} Data demonstrate the age at surgery to be an independent variable for change in the cranial index and increase in the head circumference percentile, and it is best to intervene before the age of 3 months.⁸⁰

Lambdoid Synostosis

Clinical Features

Lambdoid synostosis manifests as posterior plagiocephaly, with associated flattening of the parietal and occipital regions ipsilateral to the fused suture. Differentiating lambdoid synostosis from positional plagiocephaly is critical for determining the appropriate course of treatment for a patient (► Fig. 19.7). Significant morphological differences exist between these two entities, and an accurate diagnosis can usually be made based on the physical findings alone. The head of a child with lambdoid synostosis has a characteristic trapezoid shape, with a posteriorly and inferiorly displaced ipsilateral ear and contralateral occipital bossing. Conversely, positional plagiocephaly is associated with a head that has a parallelogram shape, with anterior

displacement of the ipsilateral ear and associated ipsilateral frontal bossing. The sequelae of lambdoid synostosis can be quite diffuse; the skull has a classic windswept appearance when it is viewed in a coronal plane.

Open Operative Technique

A number of different surgical techniques have been proposed for the treatment of lambdoid synostosis. The selected procedure should be individualized according to the manifested cranial deformities. Surgical objectives should include release of the fused suture and normalization of the posterior cranial vault. Most deformities can be corrected with the patient in the prone position and remodeling of the occipital bone alone. In those patients with significant compensatory changes in the frontal and parietal regions, an extended reconstruction of the calvaria can be undertaken, but it is very difficult to correct the protean manifestations of this disorder, and a “perfect” correction should probably not be the goal.

Endoscopic Technique

For the endoscopic treatment of lambdoid synostosis, the patient is placed prone and the horseshoe head holder is used.

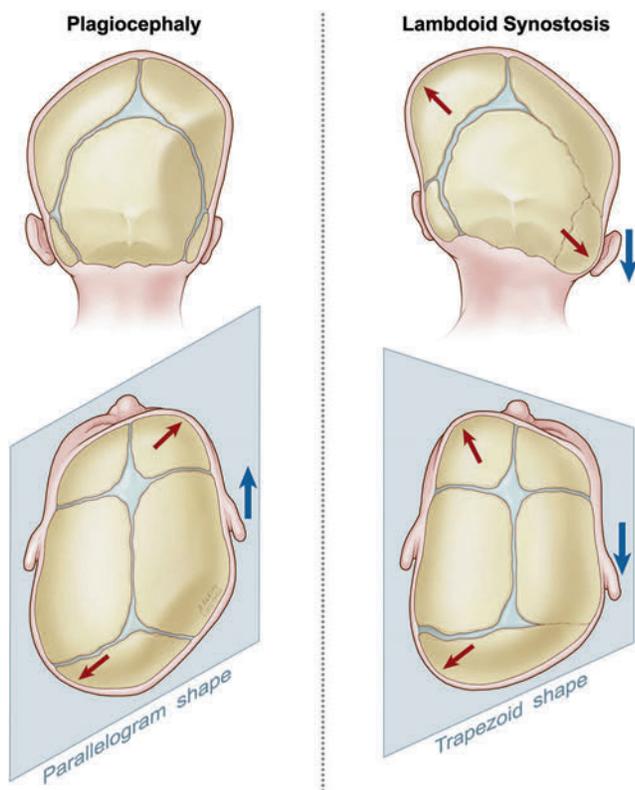

Fig. 19.7 Differentiating lambdoid synostosis from deformation plagiocephaly.

Two 2-cm incisions are made at either end of the suture. The subsequent technique is identical to that previously described. A cranial molding helmet is fitted during the first postoperative week.

Outcomes

Satisfactory results with normalization of the posterior cranial vault are seen in most infants.^{110–112} The remainder of the secondary deformity is very difficult to correct. Endoscopic results, interestingly, seem to afford better correction of the secondary skull deformity in our limited experience, likely because of the younger age at surgery.⁸⁰

19.6 Treatment Alternatives

Spontaneous resolution of a cranial abnormality without surgical intervention is unlikely in cases of craniosynostosis, making observation an inappropriate alternative in the majority of cases. In a patient who has a single-suture synostosis associated with a mild deformity that is cosmetically acceptable, especially in an older child for whom an early diagnosis was not established, conservative management may be considered. Mild deformity should not necessarily reassure the surgeon regarding brain development issues because severity does not correspond to neurodevelopmental outcomes.¹¹³

Orthotic molding has been proposed as an alternative treatment for mild cases of craniosynostosis, with the argu-

ment that helmeting is safer than surgical intervention.¹¹⁴ Until more is understood, we feel that undertaking a treatment that reduces growth in a second plane in a child who already has limited growth in another plane is an inappropriate alternative.

19.7 Complications

The importance of a skilled team, and anesthesiologists who understand the complexity of the cases, cannot be overstated. Craniosynostosis procedures are generally quite safe, with overall low morbidity and mortality rates, but tragedies are possible when the baby is not adequately resuscitated. Blood loss is the most frequently encountered complication associated with the surgical treatment of craniosynostosis. Young patients have low circulating blood volumes, and the amount of blood lost may be deceptively small when slow but persistent bleeding occurs throughout a case. A recent study has found that using tranexamic acid can significantly reduce blood loss and blood transfusion rates.¹¹⁵ Additionally, massive hemorrhage may occur with injury to a venous sinus. Adequate preparation for and monitoring of blood loss is critical in all craniosynostosis procedures. Air embolus is another serious complication that can occur in these procedures. The extensive bony work involved, along with the vascular nature of bone in young children, may lead to the incorporation of air into the vascular system. Monitoring for air emboli should be a routine component of anesthesia for these cases. Elevations in ICP may be seen in patients undergoing a reduction in skull height, and therefore this maneuver should be performed only by surgeons who truly understand the condition.

Other complications that have been observed in these procedures include transfusion reactions, complications related to anesthesia, wound infections, dural injuries, cerebrospinal fluid leakage, injury to underlying brain parenchyma, post-traumatic encephaloceles, orbital or neural injuries, postoperative hematomas, post-reconstruction calvarial defects, and seizure.

19.8 Prognostic Factors and Outcomes

Most children with nonsyndromic craniosynostosis lead normal lives after surgery. As a specialty, we have failed to develop good outcome measures for comparing the cosmetic benefits of different procedures, and we also lack neurodevelopmental outcome studies. National databases will go a long way to rectify this situation, and the parameters of care document developed by the CDC should serve as a good first step. Most neuropsychologists believe that the developmental outcomes are more profound than previously thought, and these children are not adequately studied in that regard. Perhaps the greatest service we can do for our patients is to realize that the effects of their condition may be more complicated and prolonged than originally realized, and to follow them at least until the completion of brain growth, toward 6 to 7 years of age, and longer if needed.

The specialty has also clearly gravitated toward referral to centers of excellence because the problems of these children are not as uncomplicated as previously thought. The parameters of care document outlines a master plan for following patients with craniosynostosis from the prenatal period onward.^{11,33}

Pearls

- Fused cranial sutures lead to abnormal growth of the cranial vault. Virchow’s law states that skull growth will be inhibited in the plane perpendicular to the affected suture, while compensatory growth will be enhanced in a plan parallel to it.
- Differentiating craniosynostosis from positional plagiocephaly is critical when appropriate management strategies are being determined.
- Multiple techniques are available for the surgical treatment of craniosynostosis depending on the patient’s age, severity of the deformity, and preference of the family and surgical team.
- The management of these patients can be complicated, and referral to centers of excellence should be considered.

20 Craniofacial Syndromes

Richard Hayward

The craniofacial syndromes are a heterogeneous group of rare conditions in which premature suture closure (craniosynostosis) occurs alongside other manifestations of disordered craniofacial development,¹ as well as additional skeletal abnormalities that include, in particular, those of the hands and feet.^{2,3}

The conditions seen most frequently are the eponymous syndromes of Crouzon, Apert, Pfeiffer, Saethre-Chotzen, Muenke (*FGFR3*-associated synostosis), and Carpenter, as well as craniofrontonasal dysplasia. Less commonly encountered are Antley-Bixler,^{4,5} Jackson-Weiss,⁶ and Boston-type syndromes.

The aim of care is to ensure that affected children realize their full developmental potential. Although a major component of treatment is surgical, there is now greater recognition of the needs of the child as a whole. The centers best equipped to achieve this are those that can field a multidisciplinary team; in addition to neurosurgeons, plastic surgeons, and maxillofacial surgeons, such teams include specialists in otorhinolaryngology (ear–nose–throat) and audiology, genetics, pediatrics, neurology, psychology, orthodontics, respiratory medicine, speech therapy, ophthalmology, and, of course, pediatrics—all experienced in the management of the complex problems these children so frequently have.⁷

After a brief account of the syndromes and their genetic basis, this chapter describes first the principles of management and then the complications that affected children are at particular risk for. It ends with a description of the surgical procedures most commonly deployed in the treatment of children with these complex problems.

20.1 The Syndromes

It was hoped that when the genetic basis for many of the craniofacial syndromes was discovered in the 1990s that their classification would change from the one based on the eponymous nomenclature that had been in use for so many years. Unfortunately, the situation proved to be more complex, as the genetic “overlap” between Crouzon syndrome and Pfeiffer syndrome demonstrates—a single mutation is capable of causing both Pfeiffer syndrome and Crouzon syndrome, and mutations on either of two chromosomes are responsible for Pfeiffer syndrome.^{8–10}

It therefore remains important for clinicians to recognize the typical features of each syndrome as traditionally described as well as be conversant with the underlying genetic mutations when these are known.

20.1.1 Crouzon Syndrome

Crouzon described the syndrome that bears his name in 1912. One of the more frequently encountered craniosynostosis syndromes,¹¹ it is transmitted as an autosomal-dominant condition (as with Apert syndrome, there is a significant influence of increased paternal age),¹² although it occurs with nearly equal frequency as a new mutation.

Typical features include a retruded maxilla that leaves the lower teeth projecting anterior to the upper teeth (class 3 malocclusion), a “beaky” nose, a recessed frontal region (brachycephaly) due to bicoronal synostosis, and prominent eyes (exorbitism) due to the combined recession of the infra- and supra-orbital regions (► Fig. 20.1).

Its expression is highly variable, ranging from severe exorbitism with midface retrusion and airway obstruction at one extreme to a mild prominence of the eyes at the other. The degree of craniosynostosis also varies, although the coronal sutures are most commonly affected. A catch for the unwary is that suture fusions need not be present at birth but may appear during the first 2 years of life,¹³ with a high risk for the development of raised intracranial pressure (ICP).¹⁴

Extracranial manifestations¹⁵ seen in severe cases include various types of predominantly cervical vertebral fusion^{16,17} and ankylosis affecting particularly the elbows.¹⁷

A genetically distinct type of Crouzon syndrome is associated with rugated, thickened skin and hyperpigmentation affecting particularly the flexure creases—acanthosis nigricans.¹⁸

Intelligence may be normal in children with Crouzon syndrome, but the more severe the phenotype, the more likely the child is to have developmental and learning difficulties. Marked intellectual compromise was present in 3% in the series of Kreiborg.¹⁹

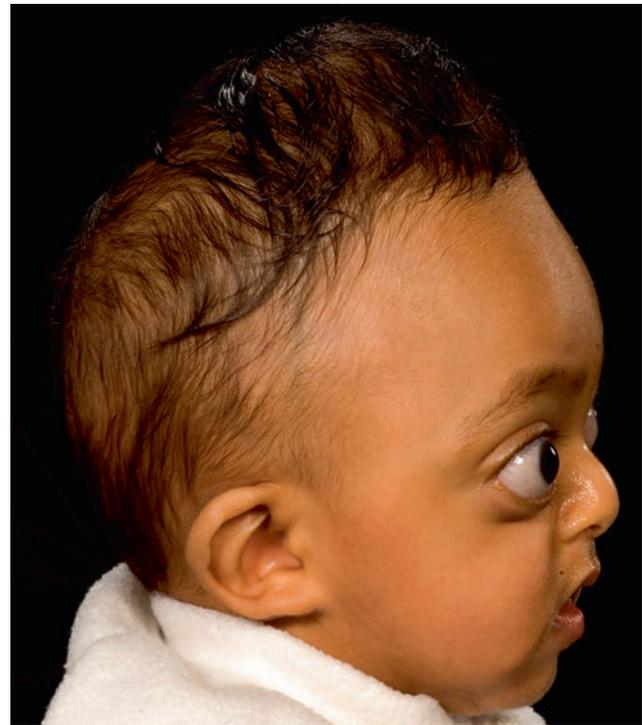

Fig. 20.1 Crouzon syndrome.

20.1.2 Apert Syndrome

Apert described the rare²⁰ condition that now bears his name in 1906.

The affected child has a head that is tall and shortened from front to back (turribrachycephaly) combined with midfacial (maxillary) retrusion, proptosis, a downward cant to the palpebral fissures, and hypertelorism²¹ (► Fig. 20.2a). The essential clinical feature, however, is complex fusion (syndactyly) of the fingers and toes^{22–24} that may require frequent surgical procedures before functional effectiveness is achieved²⁵ (► Fig. 20.2b). Visceral²⁶ and cutaneous²⁷ abnormalities can also occur.

At birth, the child with Apert syndrome may have fusion of only the coronal sutures, while the sagittal and (in particular) the metopic sutures are widely open. Fusion of all sutures, however, is progressive and usually complete before the age of 2 years.

Palatal abnormalities²⁸ ranging in severity from frank clefts to bifid uvula are common and occur with a frequency of up to 75%.^{29,30}

Cervical vertebral fusions that, like the suture fusions, are often progressive occur in more than half of affected children, although it is unusual for them to become clinically significant.³¹

Developmental and learning difficulties are the norm, although a combination of developmental assessments designed for non-Apert children with low societal expectations may overestimate their severity.³² Although a small percentage of children may complete secondary education (usually only with assistance), many drop out of mainstream education during their primary school years, and a small percentage are too severely

affected to participate in the mainstream education system at anything above kindergarten level.^{33,34} The long-term study of Allam et al of the treatment of Apert syndrome includes a description of the eventual social integration of these children.³⁵

20.1.3 Pfeiffer Syndrome

Pfeiffer syndrome is an autosomal-dominant craniosynostosis-associated syndrome characterized by suture fusions that range from bicoronal synostosis alone to pan-synostosis (with or without the cloverleaf skull deformity; see below).³⁶ Those affected have digital abnormalities,³ such as curved and shortened thumbs and great toes³⁷ (► Fig. 20.3), and (less commonly) digital fusions (but of a lesser degree than those seen in Apert syndrome³).

Cohen³⁸ divided Pfeiffer syndrome into three types based on clinical severity. Children with type 1, those least affected, may display little more than bicoronal synostosis and midface retrusion (in addition to their digital abnormalities) (► Fig. 20.4). Their neurocognitive development may be unaffected, particularly if early complications have been aggressively treated.³⁹

In types 2 and 3 Pfeiffer syndrome, the degree of midface and frontal retrusion is severe enough to obstruct the upper airway and cause ocular protrusion sufficient to threaten the corneas (► Fig. 20.5). The shortening of the skull base and crowding of the posterior fossa due to the bilateral lambdoid component of the pan-synostosis produces an increased risk for hydrocephalus. Ankylosis (bony and soft tissue) of the elbows¹⁷ and knees is common, as are fusions of the cervical vertebrae.⁴⁰

Fig. 20.3 Pfeiffer syndrome. Typical hallux deformity.

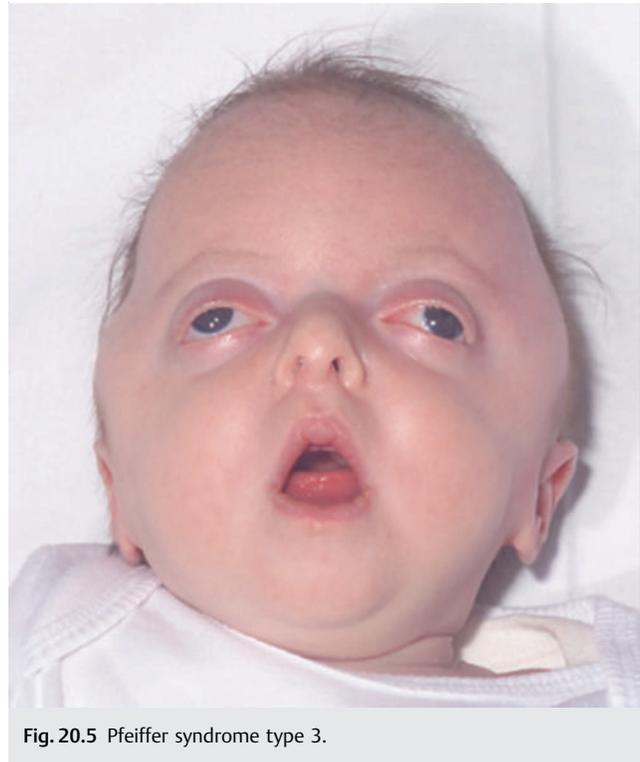

Fig. 20.5 Pfeiffer syndrome type 3.

Fig. 20.4 Pfeiffer syndrome type 1.

The difference between types 2 and 3 is that type 2 has the cloverleaf pattern of skull deformity (see below).

Neurocognitive development in types 2 and 3 Pfeiffer syndrome is usually delayed, although with active intervention aimed at improving the airway and reducing raised ICP, the outlook is not as dire as was once assumed.⁴¹

20.1.4 Cloverleaf Skull (Kleeblattschaedel) Deformity

Kleeblattschaedel anomaly, or cloverleaf skull, is the descriptive term given to a particularly severe form of synostosis-associated cranial deformity,⁴² one that poses a particular challenge for the craniofacial surgeon.^{43,44}

Although it usually occurs in association with Pfeiffer syndrome (of which it forms type 2), it can occasionally complicate Apert and Crouzon syndromes.

Cloverleaf skull is produced by a particular combination of suture fusions and raised ICP due to hydrocephalus. The sagittal and squamoparietal sutures are open, but a complex form of bicoronal synostosis results in a bony constriction band that runs posteriorly from the pterions to the lambdoids. When hydrocephalus is added to this bony pattern, the infant's skull expands upward (above) and laterally (below) the constriction band to produce a characteristic trefoil (cloverleaf) shape (► Fig. 20.6).^{38,45–47}

20.1.5 Saethre-Chatzen Syndrome

Saethre in 1931 and Chatzen in 1932 described an autosomal-dominant condition in which are combined with great

variability⁴⁸ features of coronal synostosis (uni- or bilateral), digital abnormalities that include short digits and partial syndactyly,⁴⁹ a low frontal hairline, a prominent nose, ptosis (► Fig. 20.7), and more rarely fusions of the cervical spine.⁵⁰

Complications like exorbitism and airway obstruction are uncommon, raised ICP is rarely of functional significance,⁵¹ and the neurocognitive outcome may be only modestly affected, if at all.⁴⁸

20.1.6 Muenke (*FGFR3* Mutation) Syndrome

This condition, one of the less severe of the craniofacial syndromes, is of interest because rather than being first described on the basis of the appearance of those affected, it was “discovered” during the explosion of knowledge about the genetic basis of the craniofacial syndromes that occurred during the 1990s.⁵²

Muenke syndrome has many manifestations,⁵³ but the synostosis typically affects either one or both coronal sutures.⁵⁴ Indeed, many patients previously diagnosed with isolated unicoronal craniosynostosis are now known to carry the *FGFR3* mutation.⁵⁵ Those with bicoronal synostosis typically have a broad and shallow supraorbital region with a protruding upper forehead (► Fig. 20.8).

Complications like raised ICP and airway obstruction are rare; however, although the development of a child with Muenke syndrome may be unaffected, a degree of learning difficulty is not uncommon.⁵²

Fig. 20.7 Saethre-Chotzen syndrome.

20.1.7 Craniofrontonasal Dysplasia

In this X-linked⁵⁶ syndrome (► Fig. 20.9), bicoronal synostosis (usually asymmetric in its effect) is associated with hypertelorism, wiry (“unruly”) hair, a prominent gap between the central incisors, a bifid nose,^{57–59} and sometimes abnormalities of the optic discs.⁶⁰ Development is usually unaffected, and treatment is indicated predominantly for cosmetic reasons.⁶¹

20.1.8 Carpenter Syndrome

This very rare condition⁶² is mentioned here for completeness because it is the only one of the craniofacial syndromes that has an autosomal-recessive pattern of inheritance. Also known as acrocephalopolysyndactyly because of the extra digits that form part of the clinical picture, the cranial deformity is due to various combinations of craniosynostosis.^{63,64}

20.2 The Molecular Genetics of Syndromic Craniosynostosis

With the exception of Carpenter syndrome (autosomal-recessive⁶⁵) and craniofrontonasal dysplasia (X-linked⁵⁶), the craniosynostosis-associated syndromes have an autosomal-dominant pattern of transmission. (For a summary linking the clinical

features of syndromic craniosynostosis to their underlying genetic abnormalities, see the review by Rice.¹)

The realization that many of the craniofacial syndromes are monogenetic (due to the mutation of a single gene) plus the investigation of families with several affected members led in the 1990s to an intense examination of the genes for a fibroblast growth factor group of tyrosine kinase receptors (FGFR I, FGFR II, and FGFR III) as candidate genes. These receptors are well preserved across a range of species and are involved (among many other activities) in cranial and limb development.^{66–69} It is now known that a particular position within each FGFR protein is strongly linked to craniosynostosis because mutations in their genes (*FGFR1*, *FGFR2*, and *FGFR3*) cause Pfeiffer, Apert, and Muenke syndromes, respectively.⁷⁰

Tyrosine kinase receptors straddle the cell membrane and have extracellular, transmembranous, and intracellular components. Mutations responsible for many of the craniosynostosis syndromes affect the extracellular component of FGFR II and act by provoking “gain of function”—the receptor overresponds either to its (appropriate) fibroblast growth factor (FGF) or to other (inappropriate) chemical signals.¹⁰

In contrast, mutation of the transcription factor *TWIST* gene (which is part of the FGFR signaling pathway and like the FGFs is expressed in calvarial bone⁷¹), which is responsible for Saethre-Chotzen syndrome, acts by causing functional loss.⁷²

At a molecular level, the situation is complicated by the functional diversity of the various *FGFR* mutations.⁶⁸ For example, there are a number of individual variations of (say)

Table 20.1 Genetic mutations responsible for the syndromes described in this chapter

*FGFR2*⁷³ responsible for what from a clinical perspective would be labeled Crouzon syndrome—approximately 30 have been identified to date. However, 95% of children with Apert syndrome have one of only two genetic variations on the extracellular portion of *FGFR II*.^{8,18,29,74} As already described, not only may Pfeiffer syndrome be associated with mutations in either *FGFR2* or *FGFR1*,^{9,75} but identical mutations in *FGFR2* can cause both Pfeiffer and Crouzon syndromes (► Table 20.1).⁸

Although confirmation of a particular mutation may not affect a child's immediate management, it does allow a more informed prognosis to be given to parents. Furthermore, the discovery of the *FGFR3* mutation in a child previously thought to have nonsyndromic unisutural synostosis, for example, will warn the craniofacial surgeon that a degree of relapse/reversion may occur following reconstructive surgery⁷⁶ (see below).

Knowledge of the responsible mutation also has important implications for genetic counseling. Parents who already have an affected child may wish to avail themselves of the opportunity not only for prenatal ultrasound examination of the fetus^{77–80} but also for preimplantation diagnosis when considering further pregnancies.^{81,82}

Research continues into the possibility of either gene substitution therapy following fetal diagnosis or a “vaccine” that interferes with *FGFR* function and could block some or all of a syndrome's most disabling features.⁸³

20.3 Principles of Surgical Management

It is essential that children with a craniofacial syndrome be referred to a suitably staffed unit as early as possible so that the correct diagnosis (both genetic and clinical) can be made, the risk for complications assessed, and a management plan tailored to each individual child's needs devised.

As the majority of craniofacial syndromes result from a mutation of a particular gene (usually of the *FGFR* series), it should be no surprise that such mutations continue to exert their ill effects for as long as the cranial and facial skeleton is growing. It

is this phenomenon that causes the anomalies corrected during reconstructive surgery to eventually drift toward their preoperative state despite what appeared at the time of surgery to have been a satisfactory result, even to the extent that repeated surgery is required.^{84,85} Wong et al wrote of their results of fronto-orbital surgery: “In the final analysis, the expression of the underlying genetic defect probably is the major determinant of the final fronto-orbital position despite our best surgical efforts.”⁸⁶ Or, as Kohan et al concluded in their report of twins with Pfeiffer syndrome (after each twin had received a different treatment strategy), “The genetic mutation may have overridden the different surgical interventions.”³⁹

The degree to which such reversion occurs (which is not to be confused with relapse due to the failure of bone grafts or plates and screws or any injurious effects of the procedure itself) is influenced by the severity of the gene's phenotypic expression and the age of the child when surgery is performed. Thus, reversion is seen most often in the severely affected child operated upon at a young age whose craniofacial growth is proceeding rapidly; it is less of an issue in a more mildly affected child whose growth is nearly complete⁸⁷ (and, of course, in those whose bicoronal synostosis (say) turns out to be nonsyndromic⁸⁸).

All this has important implications for the timing of surgery. If the result of a reconstructive procedure for a child with syndromic synostosis is to be stable into adulthood, it should ideally be postponed until the most active growth phase of the area being operated upon (e.g., the fronto-orbital region or the maxilla) has been completed *unless a particular functional complication demands earlier intervention*.^{89–91} This principle also holds good for the management of hypertelorism.⁹²

In practice, this means that the majority of children with Apert syndrome⁹³ and the more severe forms of Pfeiffer and Crouzon⁹³ and cloverleaf⁹⁴ syndromes may require several procedures during their early years to treat such functional issues as raised ICP, exorbitism, airway obstruction, and psychological issues related to their appearance (e.g., teasing).³⁵ In contrast, for more mildly affected children (e.g., with Saethre-Chotzen or Muenke syndrome⁷⁶), reversion is less of an issue, even after early surgery.

In brief, the complexity of decision making for children with syndromic craniosynostosis means that if they are to achieve their optimal developmental outcome, their management should be undertaken only in multidisciplinary units specializing in their care.^{51,91}

20.4 Functional Complications of Syndromic Craniosynostosis

20.4.1 Raised Intracranial Pressure

Raised ICP is a well-recognized complication of syndromic craniosynostosis.^{95,96} Its incidence is strongly related to the severity of the phenotype; raised ICP is unusual in Muenke and Saethre-Chotzen syndromes and nearly inevitable in Pfeiffer type 2 syndrome (cloverleaf skull deformity).

In a study of 49 children with Crouzon syndrome from our unit,⁹⁷ raised ICP occurred in 30. The predominant cause was craniocerebral disproportion in 17, hydrocephalus in 10, and airway obstruction in 3. It recurred in 14 of the 30 after successful treatment of the first episode, and 3 experienced a third episode. Those in whom raised ICP was first diagnosed before the age of 1 year were those in whom it was most likely to recur, although not necessarily for the same reason (e.g., the onset of hydrocephalus following a vault expansion for venous hypertension).

Marucci et al⁹⁸ studied our cases of Apert syndrome. Raised ICP first occurred at an average age of 18 months in 20 of 24 children. It was treated with vault-expanding surgery in 16, cerebrospinal fluid (CSF) diversion in 2, and relief of airway obstruction in 2. It recurred in 7 patients, on average 3 years and 4 months later.

Our experience of Pfeiffer syndrome shows a similar incidence of raised ICP requiring intervention as that in our children with Apert syndrome.⁹⁹

Raised ICP can be responsible for a progressive deterioration in vision that leads eventually to blindness.^{100,101} In one assessment of visual acuity in children with syndromic craniosynostosis, 40% had function in their better eye below a level (6/12) that would allow them to hold a driving license in the United Kingdom.¹⁰²

Whether raised ICP in syndromic craniosynostosis (in the absence of hydrocephalus) can affect cognitive development over and above the effects of other frequent complications, such as chronic airway obstruction, feeding difficulties, and failure to thrive, plus any direct effects of the mutated gene upon the brain itself, is debatable. Renier et al,^{34,95} as well as other investigators, have proposed such a connection, but it is always difficult to untangle the effects of raised ICP alone from those of other manifestations of a child's phenotype (e.g., how severely their breathing is affected). However, until more definite information becomes available, the neurosurgeon's default position must always be to assume that raised ICP left untreated can indeed impair developmental outcome.

The presence of increased ICP is suggested by:

- Clinically: bulging of still-open fontanelles; stretched sutures and craniectomy defects; in older children, headache and vomiting

- Radiologically: a generalized "beaten-copper" appearance on skull radiographs in the presence of multiple suture fusions¹⁰³; progressive ventriculomegaly and effacement of the cortical sulci on magnetic resonance (MR) images and/or computed tomographic (CT) scans¹⁰⁴
- Ophthalmologically: papilledema¹⁰⁵ with or without abnormal electrodiagnostic studies and a decrease in visual acuity¹⁰⁶⁻¹⁰⁸
- On invasive ICP monitoring, the "gold standard" for the assessment of ICP:^{95,96} It is important to recognize that the figures most often used to interpret the results of ICP monitoring in childhood (normal, < 10 mm Hg; borderline, 11 to 15 mm Hg; raised, > 15 mm Hg) are "best guesses" based on a variety of assumptions. (Understandably, the parents of healthy children are reluctant to subject them to an invasive procedure performed for essentially academic interest.)¹⁰⁹ Indeed, whether an ICP of 15 to 20 mm Hg can be responsible (in the absence of other problems) for any functional impairment is debatable.

It is important to remember that although the ICP may be normal when a child first presents, the dynamic nature of the syndromic craniosynostosis process means that ICP monitoring (which in our unit includes regular ophthalmic assessments) should continue until a child is at least 8 years old; our experience is that it is unusual for raised ICP to develop or recur at an age older than that.

Causes of Raised Intracranial Pressure in Syndromic Craniosynostosis

Although the four principal causes of raised ICP in children with syndromic craniosynostosis are considered separately here, some overlap is common. Indeed, they often interact to result in a vicious cycle (► Fig. 20.10); during active (rapid eye movement, or REM) sleep, airway obstruction and periods of apnea cause CO₂ retention, drops in SpO₂, and cerebral vasodilation that produce waves of very high pressure lasting 10 to 20 minutes superimposed upon a baseline that may be only moderately elevated (► Fig. 20.11). During these waves of high pressure (most obvious on overnight

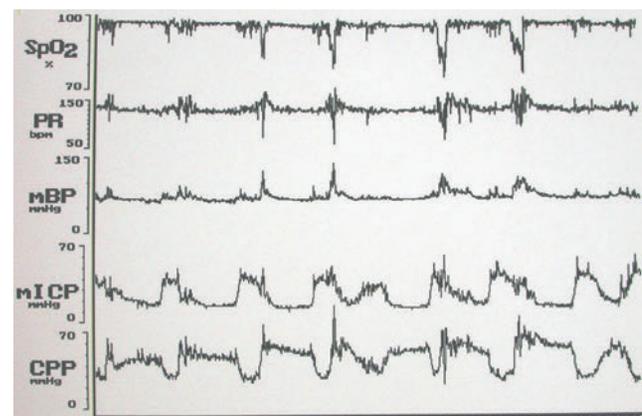

Fig. 20.10 Overnight record showing waves of elevated intracranial pressure associated with drops in SpO₂, elevations in blood pressure, fluctuations in pulse rate, and drops in cerebral perfusion pressure.

recordings), the cerebral perfusion pressure can fall to as low as 14 mm Hg.¹¹⁰

Craniocerebral Disproportion

Intracranial volume (ICV) can conveniently be measured with CT data¹¹¹ in children with¹¹² (and without¹¹³) craniosynostosis, but it has proved an unreliable predictor of raised ICP.^{114,115}

Although it was once thought that the cause of raised ICP in syndromic synostosis was restraint of the growing brain by a skull that could not adequately accommodate it, it is now recognized that this is a relatively unusual situation. Indeed, in Apert syndrome, the ICV, although normal at birth, may actually be greater than normal by the time raised ICP appears.^{113,116} Fortunately, the various forms of vault expansion surgery originally designed to increase ICV are equally effective in reducing raised ICP with a more common cause—venous hypertension (see below).

Airway Obstruction

Impairment of the upper airway is common in the severely affected child with syndromic synostosis and is an important contributor to the vicious cycle that determines ICP in these children (see Fig 20.9).¹¹⁷ The peaks of ICP that can reduce cerebral perfusion pressure to as low as 14 mm Hg are invariably associated with episodes of airway obstruction during REM sleep. The practical importance of this is that improvement in the airway (e.g., by adenotonsillectomy,¹¹⁸ a nasopharyngeal prong, or tracheostomy) may help control ICP.

Hydrocephalus and Chiari 1 Deformity

As many as 40% of children with syndromic synostosis have a degree of ventricular enlargement,¹⁰⁴ but in many it is

nonprogressive. It is important, therefore, that the craniofacial surgeon does not proceed to treatment—a shunt insertion, for example—unless ventriculomegaly is progressive and other indicators of raised ICP are present.

Hydrocephalus occurs particularly when there is constriction of the skull base and early closure of the lambdoid sutures, which explains why it occurs more frequently in Crouzon and Pfeiffer (types 2 and 3) syndromes than in Apert syndrome.¹¹⁹

Although the fourth ventricle is usually small compared with the third, our experience (and that of others¹²⁰) of endoscopic third ventriculostomy has not been encouraging, and we prefer to insert a ventriculoperitoneal shunt, particularly in a young child with very high pressure.

Constriction of the skull base, hydrocephalus and raised ICP, and herniation of the cerebellar tonsils (the Chiari 1 deformity) are linked in a cycle of cause and effect.^{119,121} The Chiari 1 deformity is seen most often in children with a constricted skull base, and although its progression (with additional buckling of the lower brainstem) is facilitated by raised ICP, it is also a risk factor for the development of hydrocephalus.¹²²

When tonsillar herniation and brainstem distortion in a child with syndromic synostosis become symptomatic (usually when respiratory studies suggest a central as well as an obstructive contribution to breathing problems¹²³; see below), a foramen magnum decompression may be needed.

Raised Venous Pressure

Intracranial venous hypertension is a major contributor to raised ICP in children with syndromic synostosis.¹²⁴ Its cause is narrowing or actual occlusion of venous channels through the skull base¹²⁵ that impedes the outflow of blood from the cranial compartment. The rise in venous pressure thus produced is aggravated by airway obstruction, and by interfering

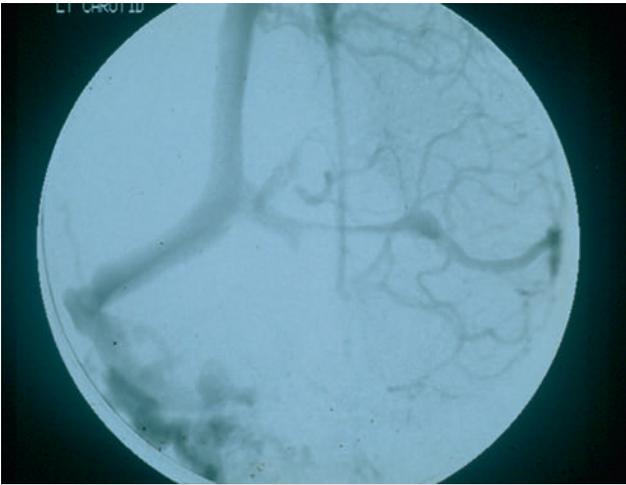

Fig. 20.12 Digital subtraction angiogram of a child with syndromic craniosynostosis showing near-occlusion of the left transverse sinus, absence of both sigmoid/jugular complexes, and a mesh of collateral veins palpable in the right retromastoid region.

with CSF absorption, it is also a potential contributor to hydrocephalus—a situation similar to that often seen in achondroplasia.¹²⁶

In a digital subtraction angiography study of 23 of our children with syndromic synostosis and raised ICP,¹²⁷ 18 had either complete or more than 50% occlusion of the sigmoid/jugular complex on one or both sides (► Fig. 20.12). Extensive collaterals through the retromastoid region and other transosseous channels can cause troublesome bleeding during reflection of the extensive skin flaps often required for craniofacial surgery.^{44,128}

Treatment would ideally either open up or bypass the obstructed venous channels. Although this has not proved successful,¹²⁹ any vault-expanding procedure will lower ICP due to venous hypertension—another example of the close relationship among the various causes of raised ICP in syndromic synostosis.

In summary, raised ICP does not develop in all children with syndromic synostosis (about 40% of our children with Crouzon syndrome and only one-third of those in Renier's series had an ICP above 15 mm Hg⁹⁵), and not all who do are best treated by cranial vault expansion. This raises questions about the policy of many craniofacial units—the routine use of the fronto-orbital advance when these children first present.

20.4.2 Airway Obstruction

Impaired respiratory function, particularly at night, when snoring is a frequent complaint, is a common problem for the more severely affected child with syndromic craniosynostosis. It is usually caused by airway obstruction due to narrowed nares, cramped nasal passages, a maxilla constricted in all planes, and tracheal softening; however, a central component occurs when there is brainstem compression from a Chiari 1 deformity.¹²³ An airway clear at birth may become obstructed during later growth of tonsillar and (in particular) adenoidal tissue in the restricted space available.

In addition to contributing to raised ICP, breathing difficulties impair the ability of the infant and young child to feed and are an important contributor to their failure to thrive. In older children, disturbed nights lead to sleepiness during the day and can interfere with schooling.

All children in whom breathing difficulties are suspected should undergo an overnight respiratory sleep study. Although the most common cause is upper airway obstruction, such a study will determine whether a central component is present; if there is a central component and it is associated with a Chiari 1 deformity, a foramen magnum decompression may be required.¹²³

Management involves (in ascending order of magnitude) the following: insertion of a nasopharyngeal airway,¹³⁰ adenotonsillectomy (which may need to be repeated as the child grows),¹¹⁸ continuous positive airway pressure (CPAP),^{131,132} tracheostomy, and finally operations that open the airway by advancing the maxilla—the Le Fort III advance (performed at an average age of 8 years in Fearon's series¹³³) and the monobloc frontofacial advance¹³⁴ with or without distraction—and widening it (the facial bipartition).

20.4.3 Corneal Exposure

Recession of the maxilla below and the fronto-orbital region above can leave the corneas exposed and in danger of permanent scarring.

Temporary measures to protect them include the instillation of lubricating drops (particularly useful when the eyes do not close completely at night) and tarsorrhaphy, although this can raise the intraocular pressure in the face of severe exorbitism. Longer-term protection requires advancement of the bony orbital rim, either in part with a fronto-orbital advance or completely with a fronto-orbital advance combined with a Le Fort III maxillary advance or a frontofacial monobloc procedure (which can in exceptional circumstances be performed as a semi-emergency procedure¹³⁵).

20.4.4 Cosmesis

The cosmetic disabilities that most trouble patients with syndromic synostosis and their families include a misshapen forehead, protruding eyes, eyes set too far apart (hypertelorism), and an upper jaw that is set back while the lower jaw protrudes.

In correcting for cosmesis alone, it is important to bear in mind the caveat already presented—that surgery carried out on a part of the craniofacial skeleton that is still growing may need to be repeated either wholly or in part in order to achieve a result that will prove stable over time. Each of the various components of the craniofacial skeleton has its own growth pattern. Waitzman et al have calculated that the cranio-orbito-zygomatic skeleton reaches more than 85% of its adult size by the age of 5 years.^{136,137} Our own policy, based more on clinical observation than on measurement, is to assume that a forehead and supraorbital region in a satisfactory configuration at around 10 years of age are unlikely to need further correction, and that cosmetic reconstructions after that age can focus more on the maxilla and mandible, where

growth will continue until secondary dentition is complete during the mid to late teens.

20.5 Craniofacial Operations for the Child with Syndromic Craniosynostosis

Paul Tessier, who was a plastic surgeon, was the first to combine the skills of the plastic surgeon and those of the neurosurgeon to create what we recognize today as the specialty of craniofacial surgery.^{138,139} Indeed, all the procedures to be described here, if not actually designed by him, were introduced with his approval and incorporated into his extensive surgical repertoire.

20.5.1 General Points

Although strictly outside the scope of this chapter, the following points should always be considered before a child with a craniosynostosis-associated syndrome is taken to surgery.

Anesthesia

Craniofacial surgery should never be undertaken without the input of pediatric anesthesiologists experienced in the pre-, intra- and postoperative care of children who may already have an obstructed airway and raised ICP, and who (because of anomalous cranial venous drainage¹⁴⁰) may be at risk for major hemorrhage during the procedure.¹⁴¹

An example of their preoperative role is providing input regarding the decision of whether a child with an obstructed airway who is about to undergo major frontofacial surgery should first have a tracheostomy.

General anesthesia for a patient with a severe facial deformity may also call for fiberoptic intubation, an essential skill for the craniofacial anesthesiologist.

The circulating blood volume of a young child is small, and losses that an older patient can withstand can lead to a swift circulatory collapse. A fail-safe approach is always to be ahead rather than behind concerning blood loss. Large-volume transfusions (one volume of circulating blood or more) will interfere with coagulation, and immediate access to fresh frozen plasma, platelets, and other clotting factors is essential.

Other ways of reducing the need for transfusion—or for the number of donors to whom the child is exposed—include the preoperative use of iron supplements (to ensure the child comes to surgery with an optimum haemoglobin level), the (still controversial) prescription of EPO (erythropoetin), and (during surgery itself) the use of cell-savers and antifibrinolytics.

Correct positioning of the patient is vital in craniofacial operations, and the anesthesiologist plays an important role in this. A head-up tilt with no obstruction of the neck veins is essential to reduce intracranial venous hypertension, although such a position will expose the patient to a (in our experience) small risk for air embolism. When surgery is performed with the patient prone, great care must be taken to protect the often protruding eyes and avoid any abdominal compression that may impede venous return.

Incision

Access

Access to large areas of the skull and face is often required in craniofacial surgery. We favor a bicoronal incision whose center lies just behind the hairline and then falls in a gentle curve to behind each ear. This provides access to the entire skull and, thanks to the pliant skin of the young, also to the upper reaches of the face. The hair need only be braided and can be left unshaved.¹⁴² Unless dissection to the zygomatic arch through the layers of temporalis fascia is required, the temporalis muscle is elevated with the skin flap. There is then no need to resuspend it at the end of surgery, and the frontal branch of the facial nerve is protected.

Cosmesis

A scar on the head is best hidden if the hair lies across it rather than being parted by it—as happens with the “classic” neurosurgical bicoronal incision, which follows the line of the coronal sutures downward to the front of the ear. Many units employ a zigzag incision to provide both hair cover and the degree of skin stretch often needed when the skull vault has been expanded.

Infiltration

For many years, we have injected a large volume of a “tumescent” solution containing two types of local anesthetic, a steroid, adrenalin, and hyalase into the proposed incision, the skin flaps, and when indicated, the tissues of the face. We have found that this reduces postoperative swelling and also shortened hospital stay.¹⁴³

Complications

Of particular importance to the craniofacial surgeon are the following.

Cerebrospinal Fluid Leaks

Dural tears are likely to occur during craniofacial operations when there has been previous surgery (particularly if metallic plates and screws have had time to migrate inward¹⁴⁴) and when the skull base is very constricted. Osteotomy cuts through the anterior skull base place the frontal extradural compartment in communication with the (bacterially contaminated) nose, allowing CSF leakage that presents as rhinorrhea. The patient is then at risk for meningitis, and contamination of the extradural space can lead to infection of the often devascularized surrounding bone.

Measures to reduce the risk for CSF leakage complicating monobloc and similar procedures include (in addition to previous experience¹⁴⁵) the following: prophylactic placement of a lumbar drain at the start or end of the operation, placement of the skull base osteotomy no farther posteriorly than the foramen cecum, careful attention to the closure of any dural tears, covering the gap in the anterior skull base before the frontal bone is replaced with a vascularized pericranial flap, and finally the use of tissue adhesive to seal the area.

Fortunately, most CSF leaks cease spontaneously. Those that show no sign of settling over a day or so should be treated by the insertion of a lumbar drain. Leaks that persist (or recur) despite this may require a formal skull base repair, either transcranially or transnasally.

Infection and the Dead Space

The monobloc procedure by definition places the frontal extradural space and the nasal cavity in communication, something that a separation of the surgical components into a fronto-orbital advance and a Le Fort III advance does not do. However, any operation that increases the ICP carries the risk of leaving an air, blood, and serous fluid-filled dead space,¹⁴⁶ which together with the often devascularized bone surrounding it provides an excellent substrate for bacterial growth.

Discussion with the hospital's microbiologists is obligatory, both to determine the most suitable antibiotic regime to be used both prophylactically and to decide when infection is either confirmed or assumed in the absence of an obvious source.

In our unit, we have a low threshold for reopening the skin incision and thoroughly washing the surgical field with an antibacterial solution if infection is suspected.

Bone Defects

Cranial vault expansion often leaves areas of bone defect that in a child older than 1 or 2¹⁴⁷ years of age are unlikely to fill in spontaneously. We regularly use a "salami" of milled bone fragments that are mixed with tissue adhesive and then "rolled out" in a thin strip to provide permanent bone cover for such defects.¹⁴⁸

For the elective closure of bone defects in the older child we use when possible split calvarial bone.¹⁴⁹

Bone Fixation

The tendency of metallic plates and screws to migrate inward¹⁴⁴ has led us to avoid their use when possible, particularly in young children in whom sufficiently rigid fixation can usually be obtained with absorbable sutures. Metal plates and screws complicate subsequent operations when they become buried in bone; they sometimes eventually penetrate the dura and make tears that are difficult to repair inevitable during subsequent operations.

20.5.2 Craniofacial Procedures

The operations involved in the management of children with craniosynostosis syndromes cross many surgical specialties. Described here are those that include a neurosurgical element wholly or in part.

Fronto-orbital Advance

The operation most frequently performed in the management of syndromic synostosis is the fronto-orbital advance, in which the frontal bone and the supraorbital ridge are brought forward a couple of centimeters or so and then fixed in their

new position. The fronto-orbital advance both expands the intracranial volume and provides cover for the upper parts of the globes. Its cosmetic effect may be all that is required in the management of less severely affected children—some with Muenke or Saethre-Chotzen syndrome, for example. At one time, it was believed that the skull base osteotomies involved would "free" the facial skeleton from the skull base, allowing the maxilla to assume a more normal trajectory—the so-called "floating forehead."¹⁵⁰ However, as discussed earlier, it is now recognized that maxillary (and fronto-orbital) growth is determined more by the patient's genotype than by the effects of any frontal and base-of-skull disconnection.^{39,86}

When both coronal synostosis and maxillary hypoplasia require attention (as in the Crouzon, Apert, and Pfeiffer syndromes), the fronto-orbital advance can be combined with a Le Fort III⁸⁹ to advance the whole frontomaxillary complex as an alternative to the monobloc procedure.

Cranial Vault Expansion

The cranial vault is expanded anteriorly as a result of both the fronto-orbital advance (see above) and the monobloc procedure. However, biparietal and posterior vault expansions are also useful ways of lowering ICP due to craniocerebral disproportion with or without venous hypertension. A posterior expansion can when necessary be taken as far down as the foramen magnum to decompress a symptomatic Chiari 1 malformation. The released parietal bones or posterior vault can be left to float freely, but a greater increase in ICP is achieved if the bones are secured in their expanded position with bone struts and absorbable sutures. The degree of expansion achievable is limited by how far the overlying skin will stretch to accommodate the expansion, although such maneuvers as "relaxing" incisions in the galea and the use of looped tension sutures can ease edge approximation. The use of springs and distraction, however (see below), addresses this issue.

A cranial vault expansion may have unintended consequences, not the least of which is the conversion of a previously large but stable ventricular size into overt hydrocephalus.¹⁵¹

Springs Technology

The use of springs to move mobilized segments of the skull into a new position was introduced into craniofacial practice by Lauritzen et al.^{152,153}

We have also found springs a convenient way of providing a greater degree of vault expansion because of their gradual as opposed to immediate intraoperative stretching of the overlying skin (► Fig. 20.13). The scale of the surgery required to insert them is often less than that of a conventional vault expansion, but another operation to remove them once bone consolidation has been achieved is usually required.

Distraction Technology

Distraction provides another mechanism for moving bone gradually over days rather than immediately during surgery. The distractors are applied after the bone cuts have been

made. The incision is closed, and then the mobilized bone segment is pulled (or pushed) a millimeter or so a day until it reaches its intended position. The distractors are retained until bone healing (consolidation) is complete¹⁵⁴ and then removed.

In craniofacial surgery, distractors have been used for fronto-orbital advances, cranial vault expansions, Le Fort III advances, and frontofacial monobloc procedures (with or without facial bipartition), in which they have been shown to provide a larger advance in terms of bone movement compared with previous techniques using immediate fixation.^{133,155–157} They are also used in stand-alone procedures to lengthen both the maxillary alveolus (Le Fort I) and the mandible.¹⁵⁸

Distractors fall into two groups—"internal" and "external." Internal distractors are effectively "ram screw" devices whose base plates are fixed to each side of the bone cuts. When the shaft of the distractor is rotated, the mobilized segment is pushed forward or backward.^{157,159} External distractors pull rather than push the mobilized bone segment. Wires attached to plates screwed to the (mobilized) bone are brought out through the skin and connected to a frame fixed by pins to the patient's head (► Fig. 20.14a,b). The frame is so constructed that it can be slowly expanded, a process that gradually pulls the bone forward. Again, once the desired amount of movement has been achieved, the wires and frame are left in position until bone consolidation¹⁵⁴ has been achieved.^{133,156}

Monobloc Frontofacial Advance

The monobloc frontofacial advance, pioneered by Ortiz-Monasterio et al¹⁶⁰ and refined by Molina,¹⁶¹ has in many units become the preferred procedure for the management of patients with complex frontofacial deformities due to syndromic craniosynostosis. It expands the ICV, provides circumferential bony cover for exposed eyes, and can open up a constricted oro- and nasopharynx.¹³⁴

The combined fronto-orbital and maxillary complex is mobilized, advanced, and then maintained in its new position with bone grafts.¹⁶² In the early experience in our unit with its use in children younger than 3 years, the high incidence of complications, including infection and CSF leakage,¹⁶³ led us to confine its use to older patients—those approaching the end of facial growth, for example.

The advent of distraction technology, however, allowed us to reassess the monobloc,¹³⁴ and although it remains a very major procedure with arguments for and against,¹⁶⁴ we (and others¹⁶⁵⁻¹⁶⁷) now deploy it even in children younger than 3 years, but only if their combination of airway obstruction, corneal exposure, and raised ICP is severe enough to justify such a major operation in such young children (► Fig. 20.14a,b and ► Fig. 20.15a–d).

Bradley et al¹⁴⁵ have provided an account of how combining the monobloc with distraction can lead to a fall in the complication rate (in particular CSF leaks). The addition of neuro-navigation to the operation has the potential to make safer the effectively “blind” osteotomy cuts through the pterygoids necessary to separate the maxilla from the skull base.¹⁶⁸

Although in theory the advance of the whole orbital circumference risks moving the globe with it, this has not proved a practical disadvantage,¹⁶⁹ and our experience has been that the monobloc has cosmetic advantages¹³⁴ over the combined fronto-orbital advance and Le Fort III procedure, which has a tendency to overlengthen the face.

Facial Bipartition

Hypertelorism has for many years been treated with a “box” osteotomy, in which the anterior rim of each orbit is mobilized, a piece of bone of the required width is removed from between them and excised, and the two orbits are then approximated and fixed in their new position.⁹² The procedure

does not alter the configuration of the maxilla, which so often is in need of attention in syndromic craniosynostosis, and the infraorbital bone cuts risk damage to the buds of the upper teeth.⁶¹

To overcome these issues, Van der Meulen¹⁷⁰ proposed the facial bipartition. The operation starts with mobilization of the frontofacial segment, as in a monobloc, but then a V-shaped piece of bone is cut from the frontonasal region, the apex of the V being at the level of the (often high-arched) hard palate. A vertical cut below this turns the V into a Y. Closure of the V brings the orbits closer together¹⁷¹ and expands the maxilla¹⁶² (► Fig. 20.16). This corrects any downward slant of the eyes and also bends the face in a convexity and forward in the horizontal plane, which makes it particularly effective for the child with Apert syndrome whose facial deformity includes hypertelorism combined with midface recession in both the horizontal and vertical planes.¹⁷²

As with the monobloc, the bipartitioned segment can, if required, be moved forward with distraction¹⁷³ (► Fig. 20.17).

20.6 Summary

The discovery of many of the gene mutations responsible for the craniosynostosis-associated syndromes has provided an explanation for what specialists in this area had observed for many years—that these conditions represent a dynamic rather than a static process.

Effective management requires a team of suitably experienced specialists who can tailor management to the needs of the individual child.

Mildly affected children can undergo primarily cosmetic procedures at a young age in the expectation that they may not need to be repeated.

For severely affected children, however, early management is concentrated upon the various complications that can prevent them from achieving their full developmental potential. These include in particular upper airway obstruction, corneal exposure, and raised ICP.

If stable long-term cosmetic results are to be achieved, final reconstruction may need to be postponed until the cessation of growth of the affected areas—the late teenage years—and the establishment of adult dentition in the case of the maxilla.

Pearls

- The craniosynostosis-associated syndromes are dynamic as opposed to static phenomena.
- The gene mutations responsible for them continue to exert their effects as long as growth continues.
- The incidence of complications such as raised ICP is strongly correlated to the particular syndrome (e.g., high in Pfeiffer syndrome, low in Muenke syndrome) and the severity of its expression.
- The more severe the phenotype, the more likely it is that the anomalies corrected in early reconstructive surgery will revert to their preoperative status.
- Affected children (and adults) should be managed only in units where a multidisciplinary team of experienced specialists is available.

21 Craniopagus Twins

Samuel R. Browd, James Tait Goodrich, and Marion L. Walker

Craniopagus is among the rarest and most complex congenital abnormalities, with a history detailed in both mythology and contemporary medical literature. The technical ability to separate craniopagus twins did not develop until 1952, and even then only one twin survived the operation. Overall outcomes have been mixed until recently, with one twin of the pair usually experiencing severe neurologic consequences and often death after separation. Although modern neurosurgical techniques have evolved, the separation of craniopagus twins continues to be one of the most challenging and risky procedures in neurosurgery. With the historical record full of surgical misadventures, the decision to separate craniopagus twins poses not only a complex surgical dilemma but rightfully an ethical and philosophical challenge, as well. As additional cases have come to medical attention, two opposing strategies for separation have emerged. As the name implies, single-stage separation involves a single marathon surgery during which physical separation is performed, although preparatory surgeries to expand the scalp may precede the separation. In the last two decades, a new strategy involving multiple-stage separation has developed. In staged separations, multiple craniotomies spread over a period of several months gradually eliminate the venous and tissue connections to permit each child to develop independent cerebral venous drainage. Both single-stage and multiple-stage separation attempts have been vocally advocated as superior, but recent cases have demonstrated improved survival and outcomes with a multiple-stage approach. In this chapter, we provide a historical and epidemiologic perspective on this condition, illustrate strategies for presurgical evaluation, discuss the techniques for separation, with an emphasis on the rationale for the multiple-stage approach, and share examples of cases deemed nonseparable with current techniques and technology. We also briefly discuss the socioeconomic impact of taking on one of these challenging cases and the ethical dilemma raised by the huge allocation of resources needed to undertake a successful separation attempt.

21.1 Craniopagus: Brief Historical Perspective

Notable recent cases and attempted separations have become worldwide spectacles, leveraging our innate curiosity about these individuals and showcasing the most difficult of neurosurgical procedures; however, the same curiosity is manifested in literature and art dating to antiquity. As in the present day, those who survived infancy became the subject of fascination for some and were feared, ridiculed, or exploited by others. The earliest documented case of craniopagus twins dates from the 15th century (► Fig. 21.1). These twins were born in Bavaria, Germany, in 1491 and were described as a *monestare* (“warning from God”).¹ In a famous case of craniopagus parasiticus in the 1770s, the twins were known as the boys of Bengal² (► Fig. 21.2). In the early 17th century, it became quite popular to place conjoined twins on exhibit in traveling road shows and circuses as “freaks” of

nature. The showmen would also produce and distribute show cards and autographed pictures, thereby generating an extra and significant source of income (► Fig. 21.3). Even in the early medical literature, conjoined twins were described as “double monstrosities.”³

Several sets of craniopagus twins have lived into adulthood, although 75% die in the perinatal period and more than 90% have died by the age of 10 years, regardless of attempts at surgical separation.⁴ The first successful craniopagus surgery in which one twin lived was in 1952–1953. Oscar Sugar, MD, and his team in Chicago undertook the separation of Roger and Rodney Brodie.^{5,6} Although Roger died 1 month after surgery, Rodney lived to the age of 11 and died of complications of hydrocephalus. The first reported case in which both twins survived was reported just a few years later, in 1957.⁷ Christine Quigley highlights the history of several cases of craniopagus twins in her book entitled *Conjoined Twins*.⁸

21.2 Classification and Demographics of Craniopagus

In 1865, Forster⁹ introduced the term *craniopagus* to define twins joined by a union of the calvaria only¹⁰ (► Fig. 21.4). The union of the cranial vault is rarely symmetric and may involve any location on the head, leading to an infinite variation of configurations. This complexity is further complicated by variations in the degree of conjoining or sharing of underlying structures like the meninges, venous sinuses, and cortex, making each case surgically unique (i.e., no two cases are ever equivalent).

Despite of the variation, several authors have attempted to classify the phenotypic archetypes seen in craniopagus. O'Connell was among the first to attempt a classification schema, describing partial craniopagus, in which a limited surface area is affected, with intact or minimal cranial defects, and total craniopagus, in which an extensive surface area is shared, with widely connected cranial cavities. O'Connell further subclassified "vertical" craniopagus ("parietal craniopagus" according to the classification of Buchholz et al.¹¹) into types 1 through 3 based on the degree of cranial rotation. More recently, Stone and Goodrich augmented the partial and total divisions described by O'Connell, defining two additional main subtypes, angular and vertical, to describe the longitudinal angle of connection, regardless of axial rotation, and the facial rotation.⁴ They suggested that this classification might be used to better predict surgical outcomes based on the complexity of the various vascular interconnections.

Craniopagus is extremely rare, occurring once in every 0.6 to 2.5 million live births.^{4,12} The causal factor(s) that lead to craniopagus remain(s) unclear, with various embryologic theories proposed for both "incomplete fission" and "fusion" types.^{10,13} Although incomplete fission of a fertilized ovum was initially presumed to be the cause of conjoined twins, more current understanding of embryology suggests that the fusion of identical twin embryos during early development is likely the cause. There are no known environmental or genetic factors. The female-to-male ratio is nearly 4:1, but for this, too, no correlative or causal factors are known.

We have previously reported an extensive review of the literature from 1919 through 2006, which noted 64 well-documented cases of craniopagus, with 41 separation attempts. Of these, 29 were performed as a single-stage separation, and 12 separations were attempted with a multiple-stage approach.¹⁴

21.3 Risk Stratification of Separation

There are many reports of intra- and extraoperative misadventures; the decision to separate craniopagus twins is one that should be undertaken with serious deliberation and forethought. Until relatively recently, the decision to separate craniopagus twins inherently led to the sacrifice of one of the twins so that the other could live more "normally." Contemporary management has evolved to the point that a separation attempt is typically offered only if there is a hope of a reasonable outcome for both twins or if the life of one or both of the twins is in danger. As technology and our understanding of the complex craniopagus anatomy has grown, it is now recognized that the presence of shared dural venous sinuses is among the most challenging issues faced in any separation attempt. Equally important is a broad understanding of the numerous other risk factors that must be assessed in an evaluation of craniopagus twins for separation. As we have discussed in other publications,¹⁶ some of the factors critical to the surgical decision making are an understanding of the degree of shared scalp, calvaria, and dura (independent dural envelopes or incomplete dural separation, also called circumferential sinus lakes), the amount of separation/interdigitation or fusion of cortex or deeper structures, the extent of shared arterial connections/cross-flow and

common venous sinuses/drainage, and the presence of paired or separate venous outflow/drainage and ventricular systems.¹⁶ We have previously proposed a scheme similar to other neurosurgical risk stratification scales (e.g., the Spetzler-Martin scale for arteriovenous malformations) by which individual cases can be evaluated to determine the surgical risk (► Table 21.1).¹⁶ Our scheme assigns point values to provide a preliminary understanding of the degree of risk associated with attempted separation; a higher score is indicative of a more difficult separation. Few will debate the benefit or detriment of separation if the surgical risk is low or high, respectively, but the decision becomes more difficult in cases that fall between the extremes; however, this scheme may help with the evaluation.¹⁷ Although not fully validated, the proposed grading scale attempts to account for the most critical variables that experience has shown to influence outcome during the perioperative period, in an effort to add objectivity to a very subjective decision. Refinement, application, and validation of the scale will occur as additional cases come to modern neurosurgical evaluation.

21.4 Preoperative Assessment

Understanding and planning for the unique anatomy present in craniopagus is one of the most important factors that lead to a successful separation attempt. Equally important, a high-quality preoperative evaluation can determine which patients are truly inoperable. In the current state, preoperative evaluation consists of clinical monitoring, imaging, and anatomical modeling. Beyond the typical neurosurgical considerations are unique physiologic perturbations that occur in craniopagus that mandate cardiac, pulmonary, and renal management plans. These children often arrive in both cardiac and renal failure and can be severely ill. It has been our experience that the metabolic differences (renal, cardiac, pulmonary, other) between the twins can be quite extreme. These systems and their function can and will change during the perioperative period, and an experienced multidisciplinary medical team is necessary to take these patients up to and through a surgical separation safely. Given the complexity of the procedures and the potential for blood loss with each operation, separations must be delayed until after the patients reach an age and body weight that will allow them to tolerate significant blood loss.

Our ability to obtain high-resolution imaging and newer techniques for modeling blood flow have revolutionized the assessment of craniopagus twins. The reconstruction of high-resolution imaging accurately demonstrates critical neural and vascular structures. Post-processing of these data sets also allows detailed anatomical models to be built of the vascular and cranial structures, aiding in preoperative planning.¹⁸ Our focus in early and later imaging series is to understand principally the venous anatomy, as this is often the most challenging issue and early imaging can help determine if separation is even plausible. Computed tomography (CT) and magnetic resonance (MR) imaging will provide a preliminary understanding of the extent of fusion and the complexity of the shared arterial and venous architecture. With this imaging, we can proceed with more complex computer three-dimensional modeling as we transition from evaluation to the surgical planning phase.

Fig. 21.5 Three-dimensional model based on computed tomographic and magnetic resonance imaging data of craniopagus twins separated at Montefiore. (Reproduced from Medical Modeling, Golden, CO, and from Douglas Cochrane, MD.)

Within the last several years, technology has afforded the ability to create detailed three-dimensional anatomical models sourced from DICOM (Digital Imaging and Communications in Medicine) data (► Fig. 21.5). Helical CT scanners can obtain high-resolution angiography that is comparable to traditional digital subtraction angiography, with these images converted to three-dimensional computer models for evaluation. The anatomical models can be customized to isolate particular anatomical features one might wish to study, such as the venous anatomy. High-resolution digital reconstructions of CT imaging combined with the three-dimensional models can help with assessment of the degree and orientation of bony fusion. This information is used in planning the surgical corridor, site of separation, and post-separation reconstruction of the cranial vault.

Highly detailed anatomical images from MR imaging provide evidence of shared cortex, ventricular anatomy, hydrocephalus/transepandyml flow, dural folds, or septa. Determining where normal and abnormal boundaries exist and having a full appreciation of each structure or vessel that is conjoined define the risk of surgery and impact the strategy employed during separation and reconstruction. The extent of shared vasculature is among the key factors in predicting successful separation. Advanced MR angiography and MR venography are able to provide crucial details regarding the vascular architecture—specifically, evidence of shared arterial communications and venous sinus, anomalous venous structures, and collateral or deep venous drainage. More experimental MR angiographic and MR venographic techniques now allow the characterization of arterial flow (vector and velocity). One can also evaluate for shared flow and determine which twin is getting the most arterial blood flow and then follow the shared changes during the staged separations.

Digital subtraction angiography remains the gold standard for assessing the complex vascular architecture seen in craniopagus patients. Angiographic studies aid in developing

the operative plan and determining which vessels should be sacrificed during surgery. Knowledge of the venous anatomy is particularly crucial at each step in a staged separation because as cortical veins are selectively pruned from the shared sinus and collateralization of the deep venous drainage occurs, new patterns of venous drainage may emerge. Preoperative planning should include a detailed analysis of arterial collateralization or cross-flow and the direction and degree of any cross-flow, identification of any shared venous anatomy or anomalous venous anatomy, and the direction and timing of venous outflow. All phases of a four-vessel cerebral angiogram, including the arterial and venous phases, should be carefully reviewed. One area of specific focus during the initial angiography session is the location of the cortical veins and their insertion points along the sagittal or shared sinus. It is critical to note any evidence of collateral/alternate venous drainage and the deep venous drainage patterns, and to determine any outflow dominance in the transverse sinuses. The external carotid circulation should be studied in detail for evidence of collateralization or retained fetal anastomosis.

Stereotactic imaging with both CT and MR has been a valuable adjunct and can be used for both preoperative planning and intraoperative guidance. Optical guidance systems are cumbersome because of the need for rigid fixation and light-of-sight issues; these can be especially problematic when the patient(s) need to be repositioned during a procedure, although newer magnetic tracking systems allow patient repositioning without loss of registration data. Functional MR imaging and positron emission tomography have been used in some cases to assess eloquent cortical areas. The practicality of functional imaging has to be assessed on an individual basis; however, any additional imaging studies that might provide useful for clinical or research data should always be considered.

21.5 Single-Stage Separation

Early neurosurgical pioneers and some contemporary colleagues advocate a single-stage operation in which the craniopagus patients are separated completely before they leave the operating room. The literature suggests that there has been limited success with single-stage separations as reported by other groups.²³ Conceptually and in practice, the surgery is undertaken as a surgical tour de force in which the case often lasts from 20 to 95 hours and involves several surgeons, who sometimes work in shifts during the procedure. Single-stage separation attempts are predicated on the presumed ability of the twins' venous drainage to function independently immediately at the time of separation. As the literature suggests, cases in which reconstruction of the sagittal sinus has been attempted²⁴ rarely meet with success because of the complexity of this procedure and the instant change in hemodynamic forces/stresses that occur when a bypass of the entire cerebral venous outflow is attempted. Our view is that the complexity of these cases almost always revolves around supporting or creating adequate venous outflow. Most commonly, one twin has reasonable outflow but the other does not. It is technically difficult, even with modern imaging techniques, to predict whether the preserved venous outflow channel can accommodate the sudden increase in

venous output at the moment of disconnection. If the surgical team is inaccurate in this assessment, a bypass must be performed (if it is not already planned for); otherwise, the patient will likely succumb to severe venous hypertension and the resultant complications, which can include stroke or death. For these and other reasons, we have favored a multiple-stage surgical approach.

21.6 Theory of Staged Separation

It is our collective opinion and experience that staging the separation affords a greater degree of safety and control than a single separation attempt. As we have discussed, the shared venous anatomy is the causal factor leading to the major surgical morbidity encountered in modern separation attempts.²⁵ Until recently, it was generally accepted that death or insurmountable neurologic deficits were to be expected in one twin secondary to the venous hypertensive bleeding that can occur during the final separation of the shared dural venous sinuses. In almost every case, the surviving twin received the entire superior sagittal sinus during separation. The twin that was lost had no suitable sinus, and either the bypass failed or the recipient's venous outflow channels were inadequate to handle the huge increase in venous outflow.

When the operations are staged, both twins can be prepared for the eventual separation with gradual occlusion of the venous outflow channels. This process of selectively pruning the venous outflow allows remodeling via collateralization of the venous outflow and the development of deep venous drainage. In contrast to acute venous occlusion, which is poorly tolerated because of venous hypertension, brain edema, and/or hemorrhage, gradual occlusion of the major venous structures is well tolerated by patients. A good analogy is a patient with a large parasagittal meningioma. These slow-growing lesions can occlude the posterior portion of the sagittal sinus, but patients rarely have venous hypertension as part of their presentation because collateral deep venous drainage has developed over time as the tumor grows. The staged approach allows the twin who will eventually be left without a functional sagittal sinus to develop a robust collateral venous drainage system that accesses the deep veins leading to the petrosal sinus or other deep venous outflow channels.

As we have previously reported,¹⁴ the process of collateralization is slow, and a staged separation generally requires many months from the initial procedure until the final separation, although the timing and length of the process will vary. To reach the final point of separation, it is now typical for craniopagus patients to undergo three to four staged procedures involving circumferential craniotomies and arterial-venous ligations. Patients are given a respite of 1 to 2 months between surgeries.²⁶

21.7 Surgical Techniques

The successful separation of twins depends on the ability to disconnect one twin from the shared sagittal or circumferential venous sinus. Most commonly, the vascular imaging studies demonstrate that one of the twins has most of the outflow to

the common sinus. The other twin generally displays evidence of a more robust deep venous collateral system. The twin with the more robust sagittal or circumferential sinus retains that structure, while the other twin (referred to as the "donor twin") undergoes forced collateralization and the development of deep venous drainage via pruning of the venous outflow to the shared sinus.

During the preliminary surgeries, several bridging veins are selected for pruning in the donor twin (► Fig. 21.6). Initially, temporary clips are placed across a bridging vein so that the venous drainage field can be monitored for evidence of venous hypertension. If brain swelling occurs or marked cortical erythema develops, indicating venous hypertension, alternate bridging veins can be selected for pruning, or the procedure can be aborted. A few bridging veins are ligated at each surgery to allow the gradual development of alternate deep venous collaterals. After partial disconnection procedures, we typically repeat MR imaging and angiographic imaging to look for changes in the venous outflow patterns in the donor twin. We repeat pruning surgeries until the donor twin is completely disconnected from the shared sinus and the final separation surgery can be undertaken.

21.8 Risks and Complications

The separation of craniopagus twins is fraught with potential complications that lead to various morbidities and potential mortality. The most dangerous risk at any given point among a myriad of possible complications is venous hypertension with subsequent intraparenchymal hemorrhage. The process of staged separation conceptually allows the development of more extensive deep venous drainage in the donor twin, mitigating this risk to some degree. At the time of surgical pruning, we strongly favor the use of intraoperative temporary clipping and inspection of the cortical areas for evidence of venous hypertension. This technique helps to prevent taking venous channels that are necessary for cortical drainage. Careful preoperative planning can assist with decisions as to which veins should be selected for pruning and how many veins should be selected at each operation. Reimaging the venous system after each surgery is critical to understand the result of a recent surgery and the changes that occur as deep venous collateralization develops over time as a direct result of the prior intervention.

Another issue associated with staged procedures is the need for the surgeon to maintain orientation, thus having a continuing knowledge of the overall anatomical location of the circumferential sinus and associated areas of conjoined brain tissue, and a concept of where the final ligation will occur.²⁶ The placement of Silastic sheets between adjacent cortical areas helps preserve the natural tissue planes and provides a means for reorientation at the time of repeated procedures.¹⁴

Fused cortical areas have commonly been reported in craniopagus twins. The strategy has been to coagulate and divide the shared cortex, and in most cases this has been well tolerated, without obvious deleterious cognitive consequences in the twins. As the degree of conjoined brain increases, so too does the risk for cortical damage (i.e., brain damage). In two cases in which we were consultants, the degree of fused brain was considered too significant and excessive for the twins to be

separated safely. Cross-filling of arterial blood between twins is also a possibility, and the surgeon must know the direction of flow and the contribution of the shared arterial branches to decide at what stage and in which location to coagulate the arteries to avoid significant ischemia. MR imaging vascular flow studies and conventional angiography can help in determining the timing and location.

Large scalp, skull, and dural defects created by the separation require reconstructive surgical repair for good functional and cosmetic outcome. As with many procedures, the dura is reconstructed with a variety of allograft products, including allograft dural substitutes. We have found, though, that the best dural defect repairs are those done with sewn-in grafts that can provide a watertight closure. If achieved, a watertight closure significantly reduces postoperative cerebrospinal fluid leaks, which can be devastating. The craniotomy flap is replaced and plated at each stage to provide stability. At the final separation, large calvarial defects can be left open for later repair, or the surgical team can fabricate split-thickness autograft to repair the defects. Some surgical teams have fabricated custom cranioplasties for later placement. Although these implants can lead to good cosmetic reconstructions of the cranial vault, the

long-term implications of a foreign body implant is not yet well documented. In our last two cases, we have repaired the calvarial defects with split-thickness grafts at the time of the final surgery, with good results to date.

Tissue expanders are used during the multiple surgical procedures to allow the growth of additional scalp, reducing the need for the incorporation of rotational or transpositional flaps.¹⁴ Tissue expanders have also been used on a longer-term basis (3 to 6 months) before a single-separation procedure.²⁷ We advise delaying the placement of the tissue expanders during staged separations until the penultimate procedure to avoid the common complication of cerebrospinal fluid leak and infection. We have also learned that the expansion can never be too large. Working with the plastic surgeons, we take advantage of every space of scalp expansion. During the final procedure, the expanded scalp will naturally contract, resulting in less tissue, so over-expansion is critical.

Despite the absence of major portions of the dura mater, falx, and superior sinuses, craniopagus twins do not present with hydrocephalus, which indicates that cerebrospinal fluid is being rerouted and adequately reabsorbed.²⁸ Gradual surgical separation, however, may alter the absorptive capacity in one or both

twins, leading to the need for cerebrospinal fluid diversion. Routine postoperative CT and MR imaging may provide evidence of hydrocephalus, and shunt placement can be carried out as the need arises. With the use of the staged procedure, the incidence of hydrocephalus requiring cerebrospinal fluid diversion has been dramatically reduced.

The potential for infection during multiple-stage surgical procedures is high, and postoperative infections can occur. Indwelling catheters, shunts, tissue expanders, and drains used during this prolonged period provide a direct route for infection. We no longer routinely use subgaleal drains, to avoid both infections and possible cerebrospinal fluid fistulas. To reduce the risk for infection, we use antibiotics routinely during and after surgery and minimize the use of potential vehicles for infection.

21.9 The Socioeconomic Ethics of Craniopagus

Beyond the ethical dilemma inherent in a surgery that has such high risk for one or both of the individuals involved, in a world with limited medical resources, the justification to separate craniopagus twins often meets with cynicism on many fronts. The cost of taking a separation attempt from work-up to discharge can run upward of 2 million dollars or more if the procedure occurs in the United States. It is also likely that the children will need further care and extended follow-up after surgery, raising the cost of care even more. Furthermore, many craniopagus twins come from developing nations, and the inability of the home country or indifference of the host nation to support such a medical feat leaves the burden to charitable individuals or organizations. The arguments presented and ethical dilemmas often raised relate to the fair allocation of resources. To put this into perspective, 2 million U.S. dollars in sub-Saharan Africa can provide over 570,000 pneumococcal vaccinations, with unquestionable benefit to the larger society as a whole. In a world with limited resources, it is not unfair to question the allocation of resources to two individuals. Nonetheless, a clear desire to help and our quest to take on the most challenging of cases and advance the practice of neurosurgery often supersedes these concerns. Yet, the cultural and religious significance associated with craniopagus twins cannot be underestimated. We have had several experiences in which families wanted no intervention because they viewed the birth as a “warning from God” or an omen. In such situations, decision making moves from the medical realm back to the medicoethical realm and becomes even more fraught with complications.

21.10 Nonoperable Craniopagus

Although surgical technology and the practice of neurosurgery are ever advancing, inoperable cases of craniopagus do occur. The factors that generally preclude operability are shared venous anatomy and less frequently shared eloquent structures. Patients with complex venous anatomy and fusion anomalies that equate to craniopagus risk stratification scores in the upper 20s are still thought to have inoperable craniopagus. As an example of shared eloquent brain, we reviewed a case of angular craniopagus twins joined side to side along the parieto-occipital regions. Imaging studies demonstrated a shared central diencephalon

with an anatomical diencephalic bridge. Because of the severity of the conjoining along the midline, it was believed the risks of surgery were unacceptably high, and separation was not performed. Another case was found to be inoperable because of an extensive shared central venous anatomy. This set of nonoperable craniopagus twins had a partial angular frontal configuration; the twins were conjoined at the forehead with a shared anterior fontanel, and both were neurologically intact. At day 25, twin B developed respiratory distress, leading to cardiac arrest. The premature death of twin B necessitated an emergency separation attempt, which was unsuccessful. With ever-improving surgical technology and continued advances in our understanding of the complex physiology in craniopagus twins, it is our hope that eventually techniques will be developed to separate those whose condition is now considered inoperable. Nevertheless, sometimes the anatomical conjoining is just too complex, with surgical attempts leading to unacceptable risks and predicted bad outcomes, such that separation will not be achievable.

21.11 Summary

The separation of craniopagus twins represents one of the most challenging neurosurgical endeavors. Advances in our ability to obtain high-resolution imaging have furthered our understanding of the complex anatomy present in these individuals and form the foundation for any attempted separation. The social, ethical, and financial considerations of attempting a separation cannot be understated. Although surgical technology and our understanding of craniopagus physiology have advanced tremendously in the more than 60 years since the first successful separation, these cases remain humbling, and patients present whose cases are still inoperable, even with modern neurosurgical techniques and understanding.

Pearls

- As technology and our understanding of the complex craniopagus anatomy has grown, it is now recognized that the presence of shared dural venous sinuses is among the most challenging issues faced in any separation attempt.
- A high-quality preoperative evaluation with clinical monitoring, imaging, and anatomical modeling can determine which patients are truly inoperable.
- When the operations are staged, both twins can be prepared for the eventual separation with gradually occlusion of the venous outflow channels. This process of selectively pruning the venous outflow allows remodeling via the collateralization of venous outflow and the development of deep venous drainage.

At the time of surgical pruning, we strongly favor the use of intraoperative temporary clipping and inspection of the cortical areas for evidence of venous hypertension to prevent taking venous channels that are necessary for cortical drainage.

- The placement of Silastic sheets between adjacent cortical areas helps preserve the natural tissue planes and provides a means for reorientation at the time of repeated procedures.
- Tissue expanders used during the multiple surgical procedures allow the growth of additional scalp, reducing the need for incorporation of rotational or transpositional flaps.

22 Open Fetal Surgery for Myelomeningocele

Nalin Gupta

Fetal surgery arose in an effort to improve the outcome of patients with specific developmental anomalies, such as congenital diaphragmatic hernia and bladder outlet obstruction, that were often fatal, either in utero or immediately after delivery.¹ Because the pathologic effects of these disorders appeared to worsen during gestation, pediatric surgeons began to realize that early intervention, preceding irreversible physiologic sequelae, could improve survival, and perhaps functional outcomes. The technical steps that were required to achieve the goal of successful fetal surgery with acceptable maternal morbidity took decades to develop, initially in a nonhuman primate model.^{2,3}

The primary difference between fetuses with open neural tube defects (NTDs) and those with other diseases is that the anomaly is not fatal if untreated, gestation is usually carried to full term, and NTDs are not usually associated with other major organ defects.⁴ This is an ethical challenge for treating physicians because the potential benefits of prenatal intervention must be balanced by well-defined risks to the fetus and the mother, who is a “bystander” with respect to the perceived benefits—that is, she undergoes significant surgical risk but accrues no direct medical benefit. The ethical considerations of fetal surgery are most analogous to living related organ transplantation.

Fetal surgery requires the active participation and interaction of several clinical teams. Each group has a specific role, with overlap often required at different points of the evaluation and treatment plan. A multidisciplinary approach is mandatory in order to accomplish the surgical goals with acceptable clinical outcomes. Regular case discussions allow a joint review of prospective patients and their preoperative considerations, as well as ongoing follow-up of postoperative patients. Extensive counseling with the patient and family is critical before the patient can be expected to reach a carefully considered decision and before informed consent can be obtained. The risks and benefits of fetal surgery, as demonstrated by the recently published results of the Management of Myelomeningocele Study (MOMS), are described later in this chapter.⁵

22.1 Rationale for Fetal Repair

Although myelomeningocele is a defect of central nervous system (CNS) development, the impact upon other organ systems contributes to a substantial burden of disease.⁶ Despite aggressive postnatal intervention, nearly 14% of children with NTDs do not survive past 5 years of age, and the mortality rises to 35% among those with symptoms of brainstem dysfunction secondary to the Chiari 2 malformation.⁷ Although 70% of affected individuals have an IQ above 80, only 37% are able to live independently as adults.⁸

Although there is a broad spectrum of severity, it is useful to separate the neurologic deficits into two groups: primary and secondary. The primary neurologic deficits are those directly caused by the arrested development of the neural placode, which usually occurs in the lumbosacral region.^{9,10} Because

neural tube closure occurs during the third and fourth weeks of gestation, the spinal cord in this region is very immature at the stage when a myelomeningocele develops. Although the structure of the spinal cord is severely disrupted at the involved level, it is unknown whether the placode is capable of further development.¹¹ The functional neurologic level is either at the same level as the vertebral anomaly or actually higher, resulting in worse neurologic function in more than 80% of patients with open NTDs.¹²

The secondary neurologic deficits in patients with spina bifida include delayed loss of motor function, worsening bowel and bladder control, and scoliosis. Magnetic resonance (MR) imaging studies of most myelomeningocele lesions following repair show a dysplastic spinal cord terminating in the overlying soft tissues at the site of the repaired defect. Because the normal dura and other dorsal tissues are absent, the surgically separated placode is almost always attached to the overlying by scar tissue. At least by radiologic and anatomical features, virtually all patients with a true myelomeningocele have a tethered spinal cord. It is unclear what factors lead to the development of new symptoms attributable to the tethered spinal cord in some patients and not in others. Another source of confusion is that the symptoms and signs typically attributed to a tethered spinal cord can be caused by other conditions, such as a Chiari 2 malformation, a spinal cord syrinx, or hydrocephalus.

22.2 Preclinical Research

Fetal surgery for a variety of conditions was systematically developed in a series of consistent steps, beginning with proof of concept in an animal model, definition of the natural history in utero, refinement of surgical techniques in test cases, and finally evaluation of efficacy in a prospective randomized clinical trial.

The theoretical advantage of fetal repair for myelomeningocele is that the neural tube is covered and protected for many months before the expected delivery date. The basis for anticipating improved neurologic function is that restoration of the dysplastic neural placode within the spinal canal isolates it from the amniotic fluid and prevents ongoing injury.^{13,14} An ideal animal model that would occur as a spontaneous lesion and allow surgical access with measurement of outcome does not exist. In order to test fetal intervention, Meuli et al surgically created a spinal cord lesion in fetal sheep at 75 days of gestation that simulated a spina bifida lesion.^{3,15,16} A laminectomy was performed to expose the fetal spinal cord at 75 days of gestation, and the pregnancy was allowed to continue. The lambs were delivered by cesarean section at 140 days of gestation. After delivery at term, the gross and microscopic appearance of the exposed spinal cord resembled a human spina bifida lesion, and the animals were incontinent and had loss of sensation and motor function below the lesion level. One group of animals with surgically created spina bifida lesions were then treated with a myocutaneous flap at 100 days of gestation. These animals were then carried to full term and had nearly normal

motor function and normal bowel and bladder control. The results of these experiments suggest that early repair of an exposed spinal cord may preserve neurologic function and may allow improvement through plasticity. Additionally, in a separate set of animal experiments, hindbrain herniation mimicking the Chiari malformation was created by creating a cerebrospinal fluid (CSF) leak in the spinal canal; hindbrain herniation was reversed by fetal repair in the lambs.¹⁷ Although provocative, these large animal experiments clearly rely on a model system that has distinct differences from the human disease.

22.3 Initial Fetal Surgery for Myelomeningocele

The first cases of fetal myelomeningocele repair were performed in 1994 with an endoscopic technique,¹⁸ followed by an open hysterotomy approach.^{19,20} These early experiences were encouraging in that some of the secondary neurologic features associated with myelomeningocele, such as hindbrain herniation and hydrocephalus, were potentially reversible.^{21–24} In the combined series of patients undergoing fetal surgery from The Children's Hospital of Philadelphia, and Vanderbilt University (Nashville, TN), 104 patients followed for at least 1 year had an overall incidence of shunting of 54%, compared with 86% in a historical control group from The Children's Hospital of Philadelphia.²⁵ The effect was most evident for those with lumbar lesions. The incidence of shunting in those patients who underwent fetal closure before 26 weeks of gestation was 42.7% but was 75% in those who had fetal surgery after 25 weeks of gestation. Although speculative, a potential mechanism explaining this improvement is that chronic CSF leakage and a reduction in subarachnoid pressure during fetal development lead to both hindbrain herniation and eventual permanent failure of CSF absorption. Interpretation of the results of these early case series was limited by selection bias and the lack of true control arm.

22.4 Management of Myelomeningocele Study

22.4.1 Study Design

Prospective randomized surgical clinical trials are difficult to conduct for a variety of reasons. The complexity, controversy, cost, and risks of fetal surgery, however, provided a stronger rationalization for examining these novel techniques in rigorous clinical trials. Other conditions treated by fetal surgery, such as congenital diaphragmatic hernia and twin–twin transfusion, have been successfully studied with a randomized clinical trial design. Therefore, once the feasibility of fetal repair for myelomeningocele and a possibility of benefit had been demonstrated in pilot studies,^{22,26–28} the logical next step was to conduct a randomized trial to determine if a real benefit was present.

The design of MOMS required an initial screening by a non-surgical coordinating center (George Washington University, Washington, DC), and if patients met the inclusion criteria, they traveled to one of three surgical institutions—The Children's Hospital of Philadelphia, Vanderbilt University, or the

University of California at San Francisco. Additional evaluation was performed at the surgical sites, and if consent was provided, the patient was randomized into either a postnatal or a prenatal treatment arm. Mothers sometimes stayed for many weeks at the study site, depending upon the development of any complications.

An unusual feature of the trial was the development of two primary clinical outcomes. First was the need for a ventricular decompressive procedure, usually a ventriculoperitoneal (VP) shunt, for the treatment of hydrocephalus. The second primary outcome consisted of a composite score derived from the Bayley Scales of Infant Development and the difference between motor function and lesion level. A great deal of planning was done to minimize the impact of bias. Because there are recognized variations in practice across the country, simply receiving a VP shunt was not a satisfactory outcome measure for evaluating hydrocephalus. Therefore, objective shunt criteria were created, and an outside panel of pediatric neurosurgeons, blinded to type of repair, were assigned to determine whether the subjects met those shunt criteria. For neurologic outcomes, the subjects were examined in a blinded fashion by an independent group of specialists not associated with any of the surgical sites.

22.4.2 Results

MOMS was halted after 183 subjects, of the planned 200, had been recruited. An interim analysis of 158 subjects who had reached 12 months of age and of 138 who had reached 30 months of age demonstrated efficacy. The two treatment groups did not differ in terms of maternal age, body mass index, or gestational age at the time of surgery. The lesion level was higher in the fetal treatment group, with 33% having a lesion at L2 or higher, compared with 17% in the postnatal group. In terms of the treatment of hydrocephalus, by objective criteria, 65% of the subjects in the fetal group met previously determined shunt criteria, compared with 92% of the postnatal group (a significant difference; $p < 0.001$). Of note, the treating neurosurgeons at the family's community were not blinded to the treatment that patient had received, and in the fetal group, only 40% actually received a shunt, compared with 82% in the postnatal group.

The difference in the second primary outcome, determined at 30 months after birth, also reached statistical significance ($p < 0.007$), with the difference between motor function and lesion level higher than expected in the fetal treatment group. The difference in the other component of this outcome measure, the Bayley Scales, was not statistically significant. The most striking difference was the presence of hindbrain herniation, with 76% of the fetal group having none or a mildly severe form and 67% of the postnatal group having a moderate or severe form (► Fig. 22.1). Finally, twice as many of the fetal group (42%) were ambulating at 30 months than of the postnatal group (21%).

The maternal risks in the fetal group were notable: chorioamniotic separation (26%), oligohydramnios (21%), need for blood transfusion at delivery (9%), placental abruption (6%), and pulmonary edema (6%). Although there were 2 fetal or neonatal deaths in each group, fully 80% of the fetal group were delivered prematurely (before 36 weeks of gestational age), compared with 15% in the postnatal group.

22.4.3 Interpretation of Results

MOMS required nearly 10 years to complete with the active participation of several large clinical and research teams. Despite its complexity, the results obtained are relatively clear. The fetal treatment group, despite having a higher lesion level, had better clinical outcomes in terms of hydrocephalus, Chiari malformation, and ambulation. Several caveats must be recognized. First, the outcomes were measured at 12 and 30 months. It is possible that these benefits are not durable and will not persist throughout life. Second, although the differences in the anatomical appearance of the hindbrain herniation and in the reduction of treated hydrocephalus appear real, whether these will result in a meaningful difference in outcome and reduction in morbidity is unknown. A long-term follow-up study of the two treatment groups from MOMS is under way, and it is hoped that it will provide some of the answers to these questions. The final important point is that the risks of the procedure are defined. These include prematurity, maternal complications, and the impact on future pregnancies. They are not to be underemphasized when fetal surgery is being considered.

22.5 Planning and Conduct of Fetal Surgery for Myelomeningocele

22.5.1 Initial Evaluation

From a theoretical perspective, fetal repair should be performed as early as possible. In practice, surgical timing is determined by the existing standards of prenatal care in normal pregnancies. Most myelomeningoceles are detected during the second trimester, either during an investigation of a positive maternal serum screening test (i.e., elevated maternal serum level of alpha fetoprotein) or during a routinely scheduled fetal anatomical ultrasound survey (usually scheduled at or after 18 weeks of gestation). The quality of current ultrasonography allows the detection of most fetuses with myelomeningoceles by the middle of the second trimester.²⁹ From a practical viewpoint, this means that a diagnosis is most often made between 18 and 22 weeks of gestation. It is unlikely that the detection of fetuses affected with spina bifida will occur any earlier unless more sensitive screening tests become widely used.

22.5.2 Preoperative Screening

Patients referred to a fetal surgery center should undergo a preliminary screening evaluation to confirm if an in-person evaluation is appropriate. An evaluation of the mother's risk as a surgical candidate requires recorded information of all physical examinations and the medical, surgical, and anesthetic history. A normal fetal karyotype is required if a patient is to be considered a potential candidate for prenatal fetal surgery. Before any decision is made by the patient and surgical team that leads to fetal surgery, a detailed evaluation at the fetal surgery center is required. This includes but is not restricted to:

- Comprehensive obstetric ultrasonographic examination, including documentation of the cervical length, placental location, fetal gestational age, degree of fetal kyphosis, level of the myelomeningocele, lateral ventricular size, presence (and severity) of a Chiari malformation, leg and foot position, lower extremity movement, and presence or absence of placenta previa or other potential contraindications to fetal or maternal surgery
- Fetal echocardiography, to exclude any concurrent/occult structural cardiac defects
- Fetal MR imaging of the brain and spine to confirm and supplement the sonographic findings
- Maternal physical examination and consultation by anesthesia and perinatology
- Psychosocial evaluation to identify maternal suitability for surgery. In addition to being screened for depression and anxiety, it is critical that the patient have adequate support available to accommodate her inability to care for herself and her other children for most of her pregnancy following prenatal surgery, and that she be capable of understanding and complying with the lifelong proscription against labor.
- Preoperative teaching about NTDs, latex allergy, and community resources; perioperative instruction regarding the surgery itself and the tocolytic program; postoperative management in the hospital; postoperative care and recommendations following discharge; prenatal care; recommendations for the continued care of the child

22.5.3 Imaging Studies

A detailed sonographic examination is able to determine a number of anatomical features with precision. These include the size of the overlying CSF-containing sac, the level of the

defect, the position of the cerebellar tonsils, the presence of lower extremity deformities, and potential concurrent non-neurologic anomalies. The limitations include difficulty in determining the number of associated brain anomalies, other intraspinal anomalies, and at times the exact dysraphic level.

Mothers should also have a fetal MR imaging study of the brain and spine. In order to minimize the effects of fetal motion, images in sagittal, axial, and coronal planes are obtained randomly by repeatedly imaging the fetus over time. The preferred MR imaging technique is a single-shot, fast spin-echo T2-weighted sequence. Evidence suggests that MR imaging may improve the ability to detect coexisting spinal and brain anomalies that may not be apparent on ultrasound studies.^{30,31}

22.5.4 Maternal Counseling and Informed Consent

In order for the patient and family to provide a truly informed consent, every effort must be made to present an unbiased and balanced description of the potential benefits of prenatal myelomeningocele repair versus the surgical risks. Potential candidates for fetal surgery should meet with all members of the team: fetal surgeon, perinatologist, pediatric neurosurgeon, anesthesiologist, social worker, and spina bifida nurse coordinator. Critical issues for discussion include the following: (1) maternal surgical risk; (2) risk for preterm birth that would otherwise be essentially nonexistent, and the sequelae of preterm birth at a variety of gestational ages; (3) details of the postoperative course, which can be quite challenging and unexpected for a previously healthy patient; (4) potential postoperative complications, such as tocolytic toxicity, pulmonary edema, blood clots, oligohydramnios, and preterm premature rupture of membranes (PPROM); (5) risk for uterine dehiscence and rupture in the setting of a fresh hysterotomy, (6) need for the avoidance of labor and the requirement for cesarean delivery in all future pregnancies; and (7) a balanced and accurate review of the outcomes reported in MOMS.

Maternal risks of the procedure are those of general and regional anesthesia, bleeding and the potential need for blood products, and intraoperative complications, including the need for fetal resuscitation and, rarely, fetal death or maternal death. Additional maternal risks include postoperative complications, such as infection, pulmonary embolism, and oligohydramnios; however, the most common complication is that of preterm labor and preterm birth. It is essential for parents to understand that a pregnancy complicated by a fetal myelomeningocele that does not undergo fetal surgical repair has the same risk for preterm birth as that of the general obstetric population—and that this risk is significantly increased by prenatal surgery with an open hysterotomy. Neurologic outcomes for infants with a myelomeningocele may be compounded by complications of prematurity that might not have otherwise happened, particularly if delivery occurs at a vulnerable gestational age. These risks are weighed against the potential benefits and the improved quality of life that those affected by spinal cord defects may experience following prenatal surgical repair.

22.5.5 Anesthetic Considerations

Open fetal procedures that require a uterine incision (e.g., myelomeningocele repair) are performed under general anesthesia,

which provides the needed uterine relaxation with the use of volatile anesthetic agents. In fact, the primary difference between fetal surgery and a cesarean delivery is that with the latter, the normal reflexive uterine contraction is relied upon to help achieve hemostasis. During fetal surgery, the same contractile force would result in inadequate blood flow to the umbilical cord and potential placental separation, which must be avoided.

The potential consequences of the profound uterine relaxation achieved with this approach to anesthesia include an increased potential for significant maternal hypotension resulting in decreased uterine blood flow and alterations in fetal hemodynamics. An epidural catheter is typically placed preoperatively for smoother emergence from general anesthesia and for postoperative analgesia. The advent of instrumentation specifically designed for fetal surgery has been critical in helping to prevent hemorrhage that would otherwise result in the setting of the necessary uterine relaxation and a fresh uterine incision.

22.5.6 Preoperative Treatment

Preoperatively, a nonparticulate antacid is given for prophylaxis against aspiration, rectal indomethacin is placed as an additional prophylactic tocolytic, and an epidural catheter is inserted. The position and efficacy of the epidural catheter are verified with a preoperative test dose (epidural placement often occurs before entry into the operating room, allowing time for a test dose). Blood products (type and crossmatch) are obtained for both mother and fetus. Sequential compression devices are placed on the mother's lower extremities to minimize the risk for deep venous thrombosis. Minimal doses of preanesthetic medications (opioids or anxiolytics) are administered in order to reduce the incidence of hypotension when maximal doses of a volatile halogenated agent are administered. When any general anesthetic is administered after approximately 20 weeks of gestation, the patient is (1) positioned with left uterine displacement and (2) adequately preoxygenated, after which (3) rapid-sequence induction and tracheal intubation are performed with cricoid pressure. Before incision, anesthesia is typically maintained with low concentrations of a volatile agent. During this time, the sonologist determines the fetal presentation and maps out the placental location and edges, additional large-bore vascular access is obtained, the urinary bladder is catheterized, and prophylactic antibiotics are administered.

22.5.7 Intraoperative Treatment

During surgery, 2 to 3 MAC (minimal anesthetic concentration) of a volatile anesthetic agent are used to provide maternal and fetal anesthesia and surgical tocolysis (uterine atony). Volatile anesthetic agents inhibit myometrial contractility by calcium-sensitive potassium channel modulation.³² The human uterus has a thick, muscular layer that is sensitive to stimulation or manipulation. Thus, uterine incision and stimulation may produce strong uterine contractions. Halogenated anesthetics cause a dose-dependent inhibition of uterine contractions and myometrial tone. Complete uterine relaxation is essential because increased uterine tone compromises uterine perfusion, especially during uterine manipulation. The increased tone increases the risk for partial placental separation. When needed,

high doses of intravenous nitroglycerin may also be used as a supplemental agent for intraoperative uterine relaxation.³³

Once hysterotomy closure begins, the inspired concentrations of halogenated agents are slowly decreased. Discontinuing a high-dose volatile halogenated agent at the beginning of surgical closure allows more time for its elimination from the tissues. To combat the increase in uterine tone that results when volatile gas concentrations are decreased, a loading dose of 4 to 6 g of magnesium sulfate is simultaneously administered intravenously over 20 minutes, followed by a continuous infusion of 1 to 2 g/h. This infusion continues for at least 24 hours postoperatively in an attempt to maintain uterine relaxation and minimize postoperative contractions (see later section on postoperative care). Intraoperatively, maternal intravenous fluids are restricted (<2 L) in order to minimize the risk for postoperative pulmonary edema, which is often associated with the use of tocolytic agents,^{34,35} particularly in the context of maternal surgery and general anesthesia. Inspired halogenated agents are discontinued once the continuous infusion of magnesium sulfate is running, and maternal anesthesia is maintained by the activation of epidural anesthesia and the intravenous administration of fentanyl and/or nitrous oxide in oxygen. If neuromuscular agents are utilized, the absence of neuromuscular blockade should be determined before tracheal extubation because magnesium sulfate potentiates neuromuscular blockade.

Whatever anesthetic technique is used for open fetal surgery, it must ensure adequate uteroplacental perfusion, profound uterine relaxation, maternal hemodynamic stability, fetal anesthesia and immobility, and minimal fetal myocardial depression and compromise. Excessive volume replacement should be avoided—particularly in conjunction with maternal tocolysis—in order to prevent maternal pulmonary edema, which has historically been a significant cause of postoperative morbidity.

22.5.8 Hysterotomy and Exposure

Successful open fetal surgery requires the execution of several critical technical steps: (1) optimizing the hysterotomy location, (2) opening the highly vascular and perfused gravid uterus with a minimum of bleeding while simultaneously preventing separation of the chorioamniotic membranes, (3) ensuring fetal stability throughout the procedure, (4) maintaining uterine relaxation, (5) achieving a watertight closure of the hysterotomy following the reinfusion of fluid into the amniotic cavity at the conclusion of the procedure, and (6) initiating aggressive intraoperative tocolysis before extubation to prevent preterm labor.¹

An epidural catheter is placed and a test dose given before the procedure, so that it is ready for use immediately postoperatively for pain control. The patient is then anesthetized with a halogenated agent for uterine relaxation. The fetus is monitored throughout with continuous intraoperative ultrasound and, when necessary, fetal echocardiography. A generously sized low transverse maternal skin incision is made and carried through the fascia and into the intraperitoneal cavity. For optimal exposure, and to prevent compression of the engorged uterine vessels, the medial portion of the maternal rectus muscles may be split and the epigastric arteries identified and ligated. The uterus is exposed and the placental location re-evaluated. If the placenta is completely anterior, the uterus will be delivered and tipped forward to allow posterior surgical access. The fetal lie is

evaluated by the perinatologist for optimal surgical positioning; if needed, an external version can be performed at this time through the relaxed, hypotonic uterus, so that the incision can be placed directly over where the fetal back is positioned. Before hysterotomy, a narcotic is administered to the fetus intramuscularly with ultrasound guidance (usually in the shoulder or rump). With care taken to avoid the placental edge, the hysterotomy is initiated with the placement of two stay sutures that will be utilized to place a specially designed absorbable uterine stapler device that provides hemostasis and seals the membranes to the myometrium.

The uterine incision is usually between 6 and 8 cm in length. After the hysterotomy is completed and hemostasis is ensured, a catheter is placed into the uterus to allow the continuous infusion of warm lactated Ringer solution around the fetus to maintain fetal temperature and avoid umbilical cord compression. With the continuous infusion of fluid, the fetus will float in the uterine cavity, which helps to push the torso upward against the open hysterotomy. This is preferred because the fetus will otherwise tend to move or drift during the surgery, which can make the neurosurgical repair difficult. The fetus is rarely removed from the uterus in order to avoid unnecessary manipulation, dehydration, hypothermia, or umbilical cord spasm. After repair of the fetal defect, a two-layer closure of the hysterotomy is begun, and several boluses of warm lactated Ringer solution are added through the catheter to restore a low-normal amniotic fluid level (as determined by intraoperative ultrasound).

22.5.9 Surgical Repair of the Fetal Defect

The anatomical features of the fetal myelomeningocele defect are visually very distinct, and determining the different structures is easier than at full term. The neural placode is always in the midline surrounded by an extremely thin layer of translucent arachnoid (► Fig. 22.2a). If the myelomeningocele sac is present, the placode is usually lifted upward away from the surface of the back. In some other situations, the placode is flat and at the same level as the surrounding skin. The epithelium of the skin does not usually reach the edge of the placode. The clear identification of the intervening arachnoid usually allows the placode to be divided from its attachments with sharp dissection.

The general steps of the actual fetal repair are very similar to those of the postnatal procedure. These include the following: (1) identification of the neural placode, (2) separation of the placode from the surrounding epithelium, (3) identification and closure of the dura, and (4) elevation of the surrounding soft tissues and closure of the skin. The major difference between the pre- and postnatal procedures is the tenuous nature of the fetal tissues. The neural placode is extremely fragile, and even limited manipulation leads to a loss of tissue integrity. Although the nerve roots are able to withstand some handling, excessive tension will cause avulsion from the placode. The dura is often insubstantial, is transparent when mobilized, and has the characteristics of arachnoid in older children. The fetal skin can withstand surgical dissection, but excessive tension leads to tearing.

The dura is loosely attached to the underlying subcutaneous tissues just lateral to the spinal canal. After the dura has been incised at its lateral junction with the dermis, gentle instillation

The fetus is not removed from the uterus, and every effort is made to maintain the amniotic fluid volume. The actual sac consists of thin membranous tissue with a minimum of skin extending upward toward the placode. (b) The skin is closed as a single layer, in this case without a patch being required. (c) After delivery at 36 weeks, the wound appears well closed, although the sutures, which are of the monofilament absorbable type, are still visible. (b) The placode was successfully mobilized, but the skin closure was supplemented with a patch. (Reproduced from Gupta N, Rand L, Farrell J, Cauldwell C, Farmer D. of saline into the epidural plane with a small angiocatheter lifts the dura away from the underlying tissues, which minimizes trauma. Between 18 to 20 weeks of gestation, the dura can be very thin and difficult to handle. After 22 weeks of gestation, the dura becomes more substantial and can be handled more easily. Once the dura is circumferentially detached from the dermis and separated from the underlying lumbar fascia, it can be closed with a running suture. If the amount of dura is insufficient, then a patch is used to close the opening. The use of acellular human dermis to repair the dura may contribute to the formation of intracellular dermoid cysts.³⁶ For this reason, a synthetic collagen matrix (DuraGen; Integra NeuroSciences, Plainsboro, NJ) can be used to create a dural barrier.

Following dural closure, the fetal skin is closed as a single layer incorporating the superficial and deeper tissues (► Fig. 22.2b). In general, dissection of the underlying muscle and fascia is not attempted because excessive fetal blood loss must be avoided and the duration of the procedure minimized. Elevation of the skin and separation from the underlying subcutaneous tissues are relatively easy, although increased tension on the skin inevitably leads to tearing. Small openings in the skin caused by handling with forceps or tension from suture

points generally close rapidly. If the skin can be brought together, the final postnatal appearance is often excellent (► Fig. 22.2c). For situations in which insufficient skin is available to close the lesion, either skin flaps, relaxing incisions, or acellular dermis can be used as a patch (► Fig. 22.3). In most cases, this patch becomes incorporated into the healing scar tissue. In general, we have avoided relaxing incisions because they often create disfiguring scars later in life.

22.5.10 Postoperative Maternal Considerations

During the first several postoperative days, uterine quiescence is maintained with the use of multiple concurrent tocolytics, and the patient is observed for associated complications during a standard surgical recovery from a major abdominal laparotomy during pregnancy. Postoperative care includes a slow reintroduction of oral intake, intravenous hydration with care to maintain fluid balance, oxygen administration by either nasal cannula or mask, electronic fetal monitoring to assess fetal well-being and uterine contractions, insertion of a Foley catheter, tocolytic therapy, and use of an epidural catheter for

pain management. The patient is unable to ambulate for at least the first 2 days postoperatively, primarily because of the presence of the epidural catheter and the effects of muscle relaxation secondary to the continuous infusion of magnesium sulfate.

Postoperative complications include pulmonary edema, oligohydramnios, PPRM, and preterm labor. Pulmonary edema is often the result of maternal fluid overload in the setting of high-dose tocolytic agents, immobility, and general anesthesia. It can be treated effectively with furosemide, but this must be administered in small incremental doses because uterine contractions will occur if the uterine muscle dehydrates too rapidly in response to a loop diuretic. Oligohydramnios may be due to a slow, occult leak of amniotic fluid from the hysterotomy site into the maternal peritoneal cavity in some patients. The amniotic fluid level may remain low indefinitely until delivery, but in a significant proportion of patients it may increase with spontaneous resealing of the leakage site. Gross rupture of the membranes is usually characterized by a vaginal gush of fluid. Although the likelihood of preterm labor is significantly increased with PPRM, there may be a significant latency period until delivery, and the patient must remain hospitalized under close surveillance for any early signs of infection (chorioamnionitis), which necessitates delivery. In the absence of significant complications, most postoperative hospitalizations last 4 to 5 days.

Preterm labor is by far the most common complication of fetal surgery. The strongest combination of tocolytics (indomethacin and magnesium sulfate) is administered in the first 48 hours following surgery. If mothers are doing well with minimal to no contractions on uterine monitoring, they are transitioned to an oral tocolytic, nifedipine. Because a fresh hysterotomy scar is stretched farther apart every day by a growing fetus, patients must remain on a tocolytic agent until they deliver. Women with a fresh hysterotomy cannot labor because of the high risk for uterine rupture. Therefore, patient education regarding the signs and symptoms of preterm labor and the recognition of abnormal contraction patterns is an essential component of discharge planning. The liberalization of activity from strict bed rest to modified bed rest to light activity depends on the patient's uterine activity.

Once all the postoperative goals have been met (ability to void and tolerate oral intake, adequate pain control, uterine quiescence, normal amniotic fluid volume, reassuring fetal heart rate tracings, postoperative teaching, ability to ambulate to the bathroom, and availability of a companion to assist in the patient's care during activities of daily living), the patient is discharged with a wheelchair and scheduled for weekly follow-up appointments. These will include an ultrasound (assessment of amniotic fluid volume, separation of the chorion and amnion, cervical length, ventricle size, and changes in the Chiari malformation; interval fetal growth can be assessed every 2 weeks), a visit to the obstetrician, and non-stress testing (NST)/antenatal testing.

Patients must deliver at 37 weeks of gestation (if they have not already delivered) because of the increased risk for uterine dehiscence and rupture with the thinning and stretching of the uterine myometrium close to term, as well as the higher likelihood of spontaneous labor. Cesarean delivery is performed via a standard low transverse uterine incision and rarely involves the fetal surgery hysterotomy site. (Proximity to the hysterotomy site, often posterior, fundal, or high, is not practical at the time of term or near-term delivery.) It cannot be overemphasized

that patients, and their primary obstetricians or perinatologists, must understand that they cannot labor in this or any subsequent pregnancy. Because the uterine defect created by the hysterotomy will never be as strong as the native tissue, patients are advised to have a scheduled cesarean delivery at 37 weeks during all future pregnancies. Inability to comply with this requirement is a contraindication to fetal surgery.

22.5.11 Postnatal Considerations

In general, the management of an infant who has undergone fetal repair is the same as that of an infant delivered at full term. A neurologic evaluation and assessment by other teams, such as urology, orthopedics, and pediatrics, are performed. MOMS required postnatal MR imaging, but this may not be required in all cases. Ventricular size at birth should be determined so that it can be followed during the initial hospitalization and after discharge.

In the lumbar region, the fetal repair usually appears well healed, and even if there are small deficiencies in the skin, they usually become covered quickly. Although we generally counsel families that a secondary repair of the skin may be necessary after delivery, this has rarely been the case. In situations in which a dural patch was used during the fetal repair, the patch itself is clearly visible but surrounded by granulation tissue at the time of delivery. During the first 2 weeks after delivery, the granulation tissue usually covers the patch, so that further closure is not required. It seems that the intrauterine environment inhibits epithelialization of the dural patch. If there is leakage of CSF, or separation of the patch, then a postnatal skin repair may be required. This is far more easily done in the postnatal period because the skin is much stronger, and the size of the defect is smaller relative to the size of the back. Before hospital discharge, the infant is referred to a spina bifida clinic for further follow-up care near the family's place of residence.

22.6 Fetal Treatment of Hydrocephalus

Fetal ventriculomegaly is easily diagnosed at 18 weeks, making hydrocephalus potentially treatable with fetal surgery. The fetal treatment of hydrocephalus was first reported in 1981,³⁷ with a number of these procedures performed in the early 1980s. Mechanical failure, complications, and frequent misdiagnosis of associated anomalies led to a voluntary moratorium on these procedures. A fundamental difficulty has been the lack of improvement that seems to be associated with fetal intervention in comparison with postnatal treatment. Several studies examining the treatment of aqueductal stenosis were identified and the results compared with those in the International Fetal Surgery Registry. The rates of survival and normal neurologic outcome were remarkably similar.^{38,39}

Although the clinical experience with fetal shunting is not encouraging, recent advances in fetal imaging, the control of premature labor, and surgical technique may leave this procedure open as an option for highly selected patients. The ideal candidate would have isolated, nongenetic aqueductal stenosis, with progressive ventriculomegaly diagnosed significantly before fetal lung maturity. The experience with fetoscopic fetal surgery

suggests that such an approach would likely be better tolerated than the ultrasound-guided percutaneous techniques used in the past. There are good reasons to be cautious. Since exclusion of associated CNS anomalies that would independently affect outcome might result in very few fetuses being eligible for this type of intervention. At present, this procedure is not being offered at our institution.

22.7 Conclusion

MOMS and pretrial experience demonstrate that fetal surgery for myelomeningocele can be performed safely, with acceptable maternal and fetal risks. Whether these risks are balanced by a benefit to the child over many years is unknown. The impact on other long-term disabilities also remains unknown and will be determined only as groups of patients are followed over time. A team approach is essential if fetal surgery is to be performed successfully.

Pearls

- Based on the results of a randomized prospective clinical trial, potential benefits of fetal surgery for myelomeningocele include reduced rates of shunt placement, and improvement in the Chiari II malformation.
- Maternal risks include premature labor, uterine dehiscence, and a requirement of Cesarean section for all future pregnancies.
- The longterm benefits of fetal intervention are not well understood.

23 Spinal Meningocele

Jennifer Strahle and Karin Muraszko

Spinal meningoceles are defined as congenital herniations of dura and arachnoid through a bony defect in the spine. Occasionally, nerve roots may be contained within the sac, but the spinal cord is usually normal and is not contained within the sac. There are multiple classifications for spinal dysraphism,¹ the most common of which separates closed lesions from open lesions. Meningocele is considered by some to be a form of closed spinal dysraphism, consisting of skin-covered defects in the vertebral arch. Closed spinal dysraphism is further divided into lesions with a subcutaneous mass and those without a mass. Meningocele usually fall into the former category, along with lipomyelomeningocele and terminal myelocystocele. Anterior and lateral meningocele usually do not have an associated subcutaneous mass because of their location. In contrast to closed spinal dysraphism, open spinal dysraphism includes cystic lesions, which are not entirely skin-covered, such as myelomeningocele, myelocele, and rachischisis.

The true prevalence of spinal meningocele is hard to measure as meningocele are often grouped with myelomeningocele.^{2,3} The total incidence of spina bifida in the United States is 0.3 to 0.4 per 1,000 live births.⁴ Spinal meningocele occur in 1 per 15,000 to 20,000 births and are less common than myelomeningocele, with less than 1 meningocele for every 20 myelomeningocele.⁵ The majority (95%) of meningocele occur in the lumbar spine, and most are skin-covered. Associated hydrocephalus is seen in fewer than 5% of cases. Many meningocele contain associated nerve roots within the sac and are therefore not technically true meningocele as the definition would suggest; rather, they represent an outward pouching of dura associated with a normal spinal cord and nerve roots. Microscopic evaluation can show ganglion cells and glial nodules as an extension from the central canal that may also be contained within the sac.³

23.1 Pathophysiology

The pathophysiology of meningocele depends upon the location and position within the spine. Posterior lumbar and posterior sacral meningocele are thought to occur secondary to defects in secondary neurulation.⁵ Anterior and lateral meningocele occur in association with generalized mesenchymal abnormalities, as may be seen with neurofibromatosis type 1 (NF-1) and Marfan syndrome. In addition, there may be a ball valve effect that results in enlargement of the meningocele sac overtime.

23.2 Classification

The term *meningocele* encompasses a heterogeneous group of mostly congenital lesions that occur adjacent to the spinal column. In the case of posterior spinal meningocele, there is a congenital herniation of dura and cerebrospinal fluid (CSF) through a bony defect in the posterior arch. Posterior meningocele occur most commonly in the lumbar and sacral spine, but they may also occur in the cervical and thoracic spine.⁶ Anterior and lateral spinal meningocele result from generalized mesen-

chymal abnormalities, and although most are congenital, they may progress and be detected postnatally. Posttraumatic or post-procedural meningocele can occur after disruption of the dura but are considered pseudomeningocele. We focus on congenital meningocele in this chapter. For purposes of this discussion, spinal meningocele are categorized based on a posterior or anterior/lateral location as well as on level of the spine (cervical, thoracic, lumbar, or sacral).

23.3 Posterior Meningocele

23.3.1 Lumbar and Sacral Meningocele Presentation

Patients with meningocele usually present after recognition of a skin-covered dorsal mass (► Fig. 23.1) and (► Fig. 23.2). Meningocele may also be diagnosed on prenatal ultrasound, although the detection rate is less than that for open spinal dysraphic lesions because there are no indirect signs such as Chiari 2 malformation (banana sign) and frontal bossing (lemon sign), which may occur with myelomeningocele.⁷ Alpha-fetoprotein levels should be normal with the skin-covered defect, in contrast to the elevated levels present with open spinal dysraphism. The neurologic examination is often normal because most meningocele contain only spinal fluid without neural tissue. However, when they are associated with other anomalies, such as tight filum terminale, tethered cord, hydromyelia, split-cord malformation, and neurenteric cyst, there may be neurologic compromise at presentation.^{8,9} Spinal meningocele may be associated with additional spinal anomalies, so it is important to obtain magnetic resonance (MR) imaging of the entire spine. MR imaging will show a dorsal fluid-filled sac that is hyperintense on T2 sequences (► Fig. 23.3). The entire spine should be evaluated because occult spinal lesions may be present in up to 81% of patients with meningocele.⁹

Differential Diagnosis

The differential diagnosis of a posterior skin-covered cystic lesion includes meningocele, lipomyelomeningocele, myelocystocele, sacrococcygeal teratoma, and pseudomeningocele. Meningocele, in contrast to lipomyelomeningocele, may transilluminate. Sacrococcygeal teratomas are located at the level of the coccyx, more caudally than most meningocele. A pseudomeningocele usually presents after prior surgery or trauma and occurs through an iatrogenic defect rather than a congenital one.

Treatment

Repair of a posterior meningocele is usually recommended at the time of presentation to prevent subsequent tethering, infection, growth of the sac, and CSF leak. Treatment of a meningocele consists of removal of the sac and repair of the defect. Although more than 90% are not associated with neurologic deficits, it is important to perform an intradural exploration and evaluate for any cord tethering before the stalk is

The *white arrow* points to the pedicle where the meningocele connected to the lumbar subarachnoid space.

amputated⁹ because there may be intradural fibrous bands extending from the spinal cord into the sac. It is occasionally necessary to perform laminectomies and explore one to two levels above and below the lesion for tethering bands. The sac may be ligated and amputated if no neural tissue is present.

Follow-up

If there is clinical concern, patients who undergo surgery for spinal meningoceles may be followed for recurrence of the meningocele or signs and symptoms of subsequent tethering, which may result in weakness, urologic changes, or scoliosis. In some cases, follow-up with MR imaging may be performed.

23.3.2 Cervical Meningocele

Cervical meningoceles are thought to arise from incomplete fusion of the posterior aspect of the neural tube when the cutaneous ectoderm fails to separate from the neuroectoderm.¹⁰ This

results in an abnormal connection of the neural tube to the skin. Cervical meningoceles, myelomeningocele, and myelocystoceles are often grouped together as cervical spinal dysraphism and account for 4 to 8% of patients with spina bifida cystica.¹¹ Cervical meningoceles represent 2% of all meningoceles.¹² There are several theories regarding the embryologic origin of these three entities, with one theory implicating limited dorsal myeloschisis as the underlying abnormality in both meningoceles and myelocystoceles¹⁰ (► Fig. 23.4). In both cases, limited dorsal myeloschisis results in an abnormal attachment of the neuroectoderm to the cutaneous ectoderm. If the central canal does not dilate, it regresses, leaving behind a band of tissue that extends to the dorsal aspect of the meningocele cavity. This band of tissue may contain glial, ependymal, or neural tissue, and its course may be either directly dorsal or lateral to one side of the meningocele sac. If the central canal remains dilated, an associated hydromyelic cavity is created that results in a myelocystocele, which distends and displaces the surrounding subarachnoid meningocele.

Fig. 23.5 Neonate with a cervical meningocele that has a wide base and is covered almost entirely by dysplastic skin. An eschar is noted at its dome (dark area).

Fig. 23.6 Posterior cervical meningocele in an infant.

A more recent classification has been proposed, and as in previous work published on cervical meningoceles, it emphasizes the presence of an intradural stalk in stratifying cervical meningoceles.¹³ This classification separates lesions with a fibrovascular or neuroglial stalk from those without a stalk. Lesions without a stalk are classified as true meningoceles. Therefore, depending on the definition and classification system used, the term *cervical meningocele* may encompass several entities—a true meningocele sac devoid of any neural tissue or a meningocele sac containing a stalk.

Cervical meningoceles usually present as a noticeable midline dorsal cervical mass (► Fig. 23.5) and (► Fig. 23.6). These lesions are usually skin-covered and rarely leak CSF.¹⁴ In contrast to lumbosacral meningoceles, cervical meningoceles may be associated with additional anomalies, such as hydrocephalus, Chiari 1 malformation, hydromyelia, lipomyelomeningocele, split-cord malformation, and Klippel-Feil syndrome.^{8,15,16} This association may reflect the relative heterogeneity of the term *cervical meningocele* because studies that separate meningoceles with hydromyelia (myelocystoceles) from meningoceles without hydromyelia suggest that true meningoceles are rarely associated with additional anomalies, such as hydrocephalus and Chiari 2 malformation.^{14,17} In addition, there are fewer associated anomalies with a true meningocele, according to the alternative classification of Salomão et al.¹³ Nevertheless, because of the association with additional abnormalities of the neuraxis, MR imaging of the brain and entire spine is indicated.^{8,15,18}

It is necessary to repair cervical meningoceles at the time of presentation because tethering by fibrous tissue extending to the dorsal aspect of the meningocele sac may lead to progressive neurologic symptoms over time.¹⁹ Operative repair involves opening the sac and performing intradural exploration for any points of tethering by fibrous bands. Goals of surgery include untethering, resection of the meningocele, cosmesis, creation of a watertight dural closure, and prevention of infection.¹⁹ Long-term follow-up was assessed in one study of four patients with cervical meningoceles.¹¹ Among the three patients with an isolated cervical meningocele, there were no long-term neurologic or urologic abnormalities. Mild orthopedic abnormalities were noted in three patients, none of which required bracing or surgery.

23.3.3 Thoracic Meningocele

Posterior thoracic meningoceles are rare and less common than lumbar or sacral meningoceles.²² In a series of 22 patients presenting with spinal meningoceles, 18% of them were in the thoracic region and 77% were in the lumbosacral region.⁹ Patients may initially present because of a skin-covered dorsal mass or present after birth with radicular pain. There are usually no neurologic deficits. Surgical treatment is similar to that for dorsal meningoceles that occur in other regions of the spine, with the primary goal of evaluating for intradural tethering bands²³ and resecting the meningocele sac.

23.4 Anterior and Lateral Meningocele

23.4.1 Cervical, Thoracic, and Lumbar Meningocele

Meningocele that occur at the anterior or lateral aspect of the spinal column result from a different mechanism than those that occur posteriorly. Anterior and lateral meningoceles are rare and are thought to result from mesenchymal disruptions, as often occurs in NF-1 or Marfan syndrome.^{24,25} These lesions have also been associated with lateral meningocele syndrome and Currarino triad (see later section on anterior sacral meningoceles). Lateral meningoceles that are not associated with either Marfan syndrome or NF-1 may be part of lateral meningocele syndrome,²⁴ which has autosomal-dominant inheritance and is associated with craniofacial abnormalities and connective tissue dysplasia.²⁶ The majority of anterior and lateral meningoceles associated with Marfan syndrome occur in the thoracic or lumbar spine, whereas those associated with NF-1 most often occur in the thoracic spine.²⁴ In the setting of Marfan syndrome, the development of dural ectasia and meningoceles is thought to occur from progressive dilation of the dura secondary to CSF pulsations distending abnormal dura.²⁷ In NF-1, meningoceles may occur secondary to trauma, dural ectasia, cystic degeneration of a neurofibroma, trauma, or congenital

herniation of dura.^{24,28} Their location in the thoracic spine may be secondary to a relatively high pressure differential between the CSF and the thoracic cavity that is due to weak paravertebral muscles.³² Anterior and lateral meningoceles are rare in the cervical spine.²⁴

Unlike posterior meningoceles, anterior and lateral lesions do not have associated skin abnormalities and may present throughout childhood and into adulthood. Growth over time may occur through the intervertebral foramen or anteriorly after erosion of the surrounding vertebral body.³³ Anterior growth may also cause respiratory failure by compression of the lung or trachea. Presentation may occur at any age and may be associated with radicular pain, weakness, respiratory compromise, or neck pain.²⁴ These lesions are often asymptomatic and may be incidental findings on imaging performed for other reasons. MR imaging should always be performed to delineate the lesion and to evaluate for associated compression or other spinal anomalies, such as associated arachnoid cysts, tethering bands, and lipoma. In the case of NF-1, MR imaging may identify a neuroma associated with the meningocele.²⁵ X-ray or computed tomography (CT) may demonstrate widened intervertebral foramina and erosion or scalloping of the vertebral bodies. There is usually no dysraphic laminar defect, as occurs with posterior lesions. On CT, the meningocele will appear hypodense, similar to CSF, and CT myelography will show a communication between the CSF spaces and the meningocele.

Treatment is indicated if a lesion is symptomatic (e.g., neurologic deficit or respiratory compromise). Asymptomatic lesions may be treated conservatively. Anterior or posterior approaches may be used, depending on the location, size, and presence of an associated neuroma.^{24,25} For most laterally directed meningoceles, a posterior approach with intradural repair is preferred. For larger lesions, an extradural lateral extracavitary approach is appropriate. For anterior thoracic lesions, an anterolateral transthoracic approach is recommended to access the lesion. Video-assisted thoracoscopy may also be used. A transthoracic–transdiaphragmatic approach or transpleural–retroperitoneal approach may be used for lesions at the thoracolumbar junction. Other treatments may include a cystopleural shunt.³³

23.4.2 Anterior Sacral Meningoceles

Anterior sacral meningoceles are rare and occur as a CSF-filled dural sac in the presacral space that connects with the spinal canal through an anterior sacral bony defect.³⁴ Most are congenital, and a female predominance has been noted.^{35,36} They are thought to arise from the agenesis of anterior sacral elements.³⁷ Although most often sporadic, anterior sacral meningoceles may display an autosomal-dominant inheritance pattern with variable penetrance.^{38,39} They may also be associated with Currarino syndrome—the triad of anorectal stenosis, sacral bony defect, and presacral mass.⁴⁰ The presacral mass is often a meningocele, teratoma, or epidermoid or dermoid cyst. A recent review of the Currarino triad noted five patients with tethered cord or anterior myelomeningocele,⁴¹ and it is possible that some anterior sacral lesions thought to be meningoceles actually contain nerve roots or neural structures.

Anterior sacral meningoceles may present earlier than anterior and lateral meningoceles in the thoracic spine. A presenta-

Fig. 23.7 Characteristic scimitar deformity of the sacrum seen in anterior sacral meningoceles.

tion with constipation may be due to the direct compression of pelvic structures or secondary to tethering of nerve roots or the spinal cord. Other presenting signs include headaches resulting from intracranial hypotension secondary to CSF accumulation in the meningocele.²⁴ Urinary dysfunction and back or radicular pain are also possible. Female patients may present during pregnancy with dystocia, and in the past, this was a cause of significant mortality due to rupture of the meningocele during delivery.³⁶ Prenatal diagnosis is rare.⁴² There is no cutaneous mass or abnormality; however, a mass may be palpated during an abdominal, a rectal, or a vaginal examination. In any newborn presenting with constipation, a thorough rectal examination should be performed. X-rays may show the classic scimitar sign of the pelvis; this results from a lack of pelvic development on one side, which leaves a contralateral area of bone in the shape of scimitar (► Fig. 23.7). Despite the large bony defect, the neck of the meningocele is often much smaller.^{34,35} MR imaging will differentiate other presacral masses, such as teratomas and epidermoid or dermoid cysts, and will also show a tethered cord if present (► Fig. 23.8). On CT, the meningocele will appear hypodense, similar to CSF. CT myelography will show a communication between the CSF spaces and the meningocele (► Fig. 23.9). As anterior sacral meningoceles may be inherited, some recommend screening immediate family members with a lumbosacral X-ray.³⁸

Anterior sacral meningoceles are generally surgically treated if the patient becomes symptomatic, such as with severe constipation. Incidentally discovered anterior sacral meningoceles can be followed conservatively, although precautions during pregnancy, such as delivery via cesarean section before labor, are advised. Treatment is complex and is usually performed through a posterior approach. Often, functional nerve roots are present along the anterior wall. When possible, ligation of the sac should be performed in symptomatic patients, provided there are no traversing nerve roots through the neck of the sac. If nerve roots are present in the neck of the sac, they should be preserved and the dura approximated around the nerve roots. If spinal cord tethering is present, untethering of the cord should also be performed. A subsequent anterior approach may

also be necessary, particularly if a diverting colostomy is needed or, in rare cases, if the meningocele is associated with an expanding mass such as a teratoma or an epidermoid or a dermoid cyst. Cyst aspiration alone should not be performed because of the risk for meningitis and failure to treat the underlying abnormality.

The prognosis following repair of an anterior sacral meningocele is good. Follow-up with MR imaging is helpful to demonstrate obliteration of the fistula.

23.5 Meningocele Manqué and Atretic/Rudimentary Meningoceles

A meningocele manqué is a spinal meningocele that initially forms in the embryo but does not develop into a cystic mass. This term was originally introduced by Lassman and James in 1977.⁴³ They described fibrous dorsal bands with or without nerve roots that tethered the spinal cord to the dorsal dura or penetrated through the dura adhering to the lamina. These lesions are associated with a tethered cord in 84% of cases and split cord in 74% of cases. Cutaneous stigmata are present in 68%, the majority in the lumbar spine.⁴⁴ They are often discovered while other dysraphic lesions, such as split-cord malformations, are being treated. The dorsal bands may extend past the dura to the skin, and this should be taken into account when the lesion is accessed because there may be tethering from the skin to the spinal cord.

An atretic or rudimentary meningocele occurs after a spontaneous arrest in the development of a meningocele, where there remains an abnormal attachment of the neural tube to the skin.⁴⁵ A cutaneous outward pouching or cutaneous stigmata remain, and meningotheelial elements are found in the skin and subcutaneous tissues.⁴⁵ There is often a bluish hue to the lesion (► Fig. 23.10a). There may or may not be a bony defect. These patients should undergo MR imaging because there may be a communication with the dura, as in a meningocele. However, imaging is often normal (► Fig. 23.10b).

Pearls

- Patients with meningoceles usually have normal neurologic function.
- Associated hydrocephalus or Chiari 2 malformation is rare.
- MR imaging of the entire spine should be performed at the time of presentation to assess for additional spinal lesions.
- Intradural exploration of the meningocele is necessary to identify any tethering bands.
- Anterior and lateral thoracic meningoceles are often associated with NF-1 or Marfan syndrome and require treatment only if symptomatic.
- Although often sporadic, anterior sacral meningoceles may be inherited or associated with Currarino syndrome.

24 Myelomeningocele

Mark S. Dias and Elias Boulos Rizk

Myelomeningocele (MMC) represents a primary failure of neurulation and results in an exposed segment of spinal cord on the back of an infant; MMC is the most severe central nervous system (CNS) malformation compatible with life. Improved nutrition and periconceptional folate supplementation have significantly reduced the incidence of this disorder. Improved treatments, including valved shunt systems for hydrocephalus, surgical treatments for symptomatic Chiari malformations and spinal cord tethering, clean intermittent catheterization (CIC) of the neurogenic bladder, and orthopedic surgical procedures and external orthoses to improve ambulation and mobility, have greatly improved the outlook for these children; many are entering adulthood, and transitional issues have consequently assumed significance. This chapter reviews various facets of MMC in childhood.

24.1 Embryology and Genetics of Myelomeningocele

Open neural tube defects (NTDs), such as MMC and anencephaly, are primarily caused by a localized failure of neurulation,¹ although a few may arise from overdistention of a previously closed neural tube.^{2,3} NTDs in animals have been produced by teratogens (reviewed by Campbell et al⁴), genetic mutations (reviewed by Copp et al^{5,6}), and experimental manipulations (reviewed by Schoenwolf and Smith⁷), although the cause of human malformations remains unknown. NTDs are likely etiologically heterogeneous^{4-6,8} and represent the end result of a variety of embryonic disorders.

The importance of genetic factors is supported by the increased prevalence of NTDs among certain ethnic groups,⁹⁻¹¹ in association with certain genetic syndromes¹²⁻¹⁵ and chromosomal defects,¹⁵⁻¹⁹ and among families with NTDs.^{9-11,20} Over 200 genetic mouse models with NTDs have been identified.^{21,22} Candidate genes are involved in the retention and metabolism of folate²³⁻²⁸ and vitamin B₁₂,²⁹ the methylation cycle and transsulfuration,^{26,28,30,31} glucose transport and metabolism,³² oxidative stress,³³ retinoid metabolism, transcription factors, and DNA repair. Folate (vitamin B₆) is particularly important. Periconceptional folate reduces both the incidence of NTD among women who have not previously had an infant with NTD (400 µg/d) and recurrences among those with a previously affected pregnancy (4,000 µg/d).^{34,35} Folate and its metabolites are involved in purine and pyrimidine synthesis and the transfer of methyl groups during the metabolism of methionine and homocysteine (► Fig. 24.1). Maternal or fetal mutations of enzymes involved in this “methylation cycle” (► Fig. 24.1) may produce methionine deficiency and/or homocysteine excess that can be overcome with supplemental dietary folate.³⁶⁻³⁸ Teratogens like valproic acid disrupt these metabolic pathways.^{38,39} Folate-dependent developmental regulatory genes coding for transcription and cell cycle checkpoint factors may also be involved.

The Chiari 2 malformation is likely an embryologically “acquired” malformation. One theory has proposed that venting of

fluid during early embryonic development causes the formation of a smaller posterior fossa from mesenchyme; subsequent growth of the cerebellum within a small posterior fossa leads to downward and upward displacement of the cerebellum and brainstem, “beaking” of the midbrain, and enlargement of the tentorial notch, as well as disordered neuronal histogenesis resulting in callosal dysgenesis, cortical heterotopias, and stenogyria (see box “Chiari-Associated Central Nervous System Malformations”).⁴⁰⁻⁴² The posterior fossa herniation may be reversible following fetal MMC closure at up to 28 weeks of gestation, although the associated cerebral malformations persist.⁴³

Chiari-Associated Central Nervous System Malformations

- Disorders of the skull
 - Lückenschädel (“skull with gaps”)
 - Small posterior fossa
 - Low-lying tentorium cerebelli with large incisura
 - Scalloping of the petrous bone
 - Shortening of the clivus
 - Enlargement of the foramen magnum
- Disorders of the cerebral hemispheres
 - Polymicrogyria
 - Cortical heterotopias
 - Dysgenesis of the corpus callosum
 - Large massa intermedia
- Disorders of the posterior fossa
 - Descent of the cerebellar vermis through the foramen magnum
 - Caudal displacement of the pons and medulla

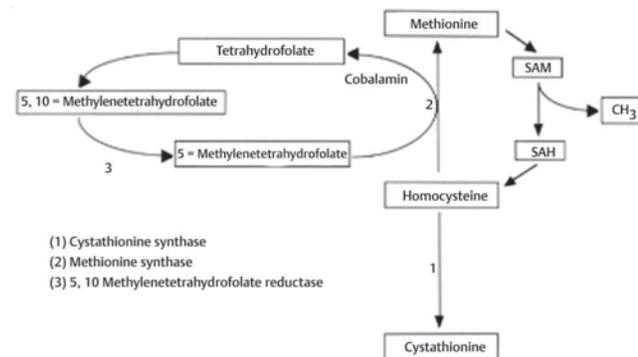

Fig. 24.1 Homocysteine/methionine cycle. The conversion of homocysteine to methionine is mediated by the donation of a methyl group from 5-methyltetrahydrofolate; in the process, tetrahydrofolate is formed. This reaction is catalyzed by the enzyme methionine synthase; cobalamin (vitamin B₁₂) is used as a cofactor. 5-Methyltetrahydrofolate is regenerated from tetrahydrofolate with 5,10-methylenetetrahydrofolate used as an intermediary, completing a “folate cycle.” Methionine is subsequently used as a “methyl (CH₃) donor” in a variety of important metabolic reactions and is converted to homocysteine in the process. SAM, S-adenosylmethionine; SAH, S-adenosylhomocysteine.

- Rostral displacement of superior cerebellum through the tentorium
- “Kinking” of the brainstem
- Loss of pontine flexure
- Aqueductal stenosis or forking
- “Beaking” of the tectum

24.2 Epidemiology of Myelomeningocele, Prenatal Diagnosis, and Counseling

The incidence of MMC is approximately 0.7 to 0.8 per 1,000 live births, with regional variations. The rate in the United States is between 0.3 and 1.43 per 1,000 live births^{44,45} and is lower among African Americans than Caucasians. The incidence of MMC has declined⁴⁶ because of improved maternal nutrition, folate supplementation, elective terminations, and other unknown factors. In the United States, the rate dropped from 0.6 to 0.3 per 1,000 live births between 1984 and 1992,⁴⁴ with little additional decline as of 2004.⁴⁷ The recurrence risk is 1 to 2% among parents having a single previously affected child,^{4,46} and 10% for those having two previously affected offspring.⁴⁸ A woman with MMC has a 3% risk of bearing an affected child.⁴

Although these are most often isolated malformations, autosomal-dominant, autosomal-recessive, and X-linked-recessive transmissions exist.⁴⁹ On the other hand, one study demonstrated a low concordance rate between monozygotic twins.⁵⁰ Human NTDs are likely polygenic.

24.2.1 Prenatal Diagnosis

Maternal serum alpha fetoprotein screening is performed at 16 to 18 weeks of gestation and is 75% sensitive for detecting open

NTDs (anencephaly and/or MMC).⁵¹ Underestimated gestational age, multiple pregnancies, and other fetal disorders, such as omphaloceles, can produce false-positive results; closed, skin-covered spinal malformations, such as myelocystoceles, may also be missed. Fetal ultrasound confirms the diagnosis with a sensitivity approaching 100% in recent series.⁵¹ Direct visualization of the placode and bony abnormalities, or indirect cranial signs such as the “lemon” and “banana” signs (► Fig. 24.2a,b) may be seen; the lemon sign has a sensitivity of 80% and the banana sign a sensitivity of 93%, with a false-positive rate of 0.88%.⁵¹ Amniotic alpha fetoprotein, acetylcholinesterase, and chromosomal analysis may be obtained via amniocentesis. Amniotic alpha fetoprotein levels are elevated in 97% of patients with NTDs,⁵² but acetylcholinesterase measurements are 14% more sensitive than alpha fetoprotein.⁵¹ False-positive elevations of both may occur with fetal blood contamination during sampling, impending fetal death or autolysis, and fetal abdominal wall defects⁵¹; false-negatives are seen with skin covered malformations.

24.2.2 Prenatal Counseling

Prenatal counseling should deliver *accurate information* upon which parents can make *informed decisions*. Almost all children survive with proper treatment^{53,54}; deaths in infancy are most commonly caused by the Chiari malformation and in later life by unrecognized shunt malfunction. The overall long-term mortality is between 24 and 60%, with a mortality of between 15 and 34% in the first 5 years and of 9 to 26% thereafter.^{55,56}

A normal IQ is attained by 70 to 75%^{56,57}; some studies suggest a lower IQ for those with hydrocephalus.^{58–66} Sixty percent of those with a normal IQ have learning disabilities,^{60,67,68} Despite many challenges, 82% of adults are independent in activities of daily living and 30% attend or have finished college, but only 32% are gainfully employed.⁶⁹ Achievement in one study

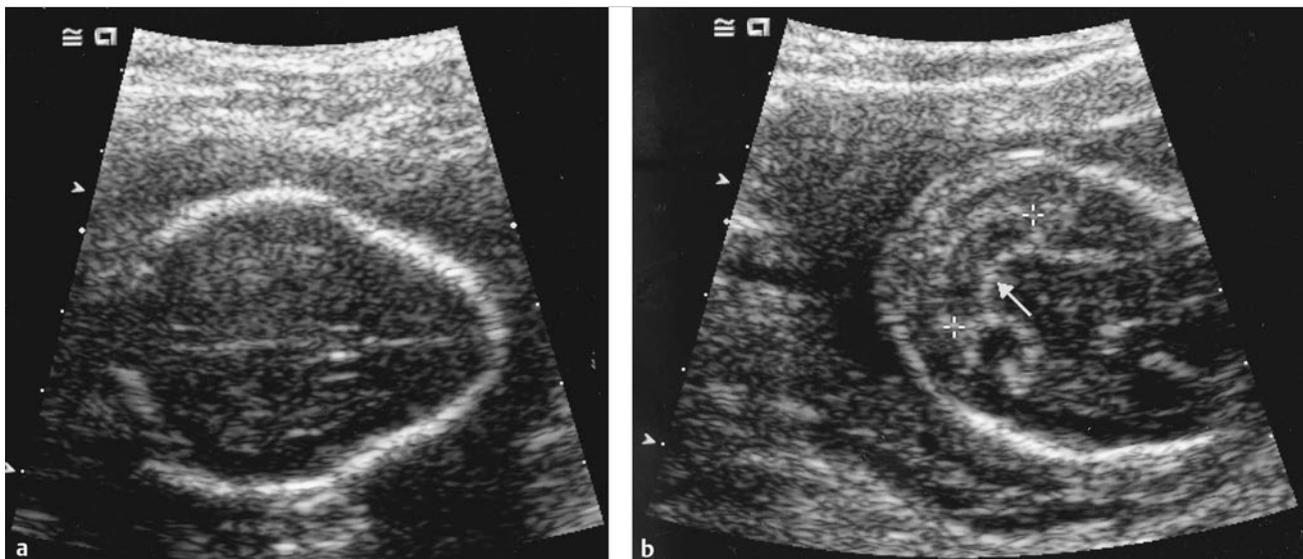

Fig. 24.2 Prenatal cranial ultrasound signs associated with myelomeningocele. (a) Lemon sign (convex inward frontal bones). (b) Banana sign (Chiari malformation).

was attained by 89% of those who never had a shunt placed, 69% of those with shunts but no revisions, 50% of those with shunt revisions before 2 years of age, and 18% of those having shunt revisions beyond 2 years of age.⁶⁵

Ambulation correlates with sensorimotor level.⁷⁰ Excluding 13% with severe delays, 89% of preadolescent children are community ambulators, including most with lumbosacral lesions and 63% of those with upper lumbar lesions.⁶⁷ Ambulation falls to below 50% in adolescence as wheelchair use becomes more efficient.⁵⁸ Few patients with lesions at L3 or a higher level are functional long-term ambulators.⁷¹

Urinary social continence (in social situations) is achieved in about 80 to 85% of school-age children.^{53,56,72-74} CIC is reported in 85%.⁵⁶ Complete bowel continence is achieved in 50% of patients, and almost 90% report continence 75% or more of the time.⁵⁶ About two-thirds of boys report at least some genital sensation, and 70 to 75% achieve reflex erections.

Approximately 70% of children require a ventricular shunt.^{53,58,67} Shunt malfunction occurs in 30 to 40% within 1 year, 60% within 5 years, and 85% within 10 years,^{58,75} and shunt infection occurs in 11 to 26%.⁷⁶⁻⁷⁸ One-third of children will undergo a tethered cord release, 15 to 33% a Chiari decompression, and 1 to 5% an operation for syringomyelia. Orthopedic and urologic procedures are also frequently required.

Cervicothoracic MMCs deserve special mention because the prognosis for sensorimotor function in these children is not predicted by their anatomical level. Most have no identifiable sensorimotor abnormalities at birth, although subtle impairments may become apparent over time; most develop hydrocephalus. Fetal magnetic resonance (MR) imaging is recommended before parents are counseled, especially if termination is being considered.⁷⁹

The best mode of delivery is not clear; studies have produced conflicting results.⁸⁰⁻⁸⁸ Although two nonrandomized studies showed better outcomes following cesarian delivery,^{80,82} five other nonrandomized studies showed no consistent benefit to cesarian over vaginal delivery except perhaps in cases with a breech presentation or significant hydrocephalus.^{81,84-87} Finally, parents should be counseled about the increased risk for MMC with subsequent pregnancies and the need for periconceptional folate (4,000 µg of folate daily, 10 times the amount recommended for the general population).³⁵

24.3 Neurosurgical Management of Children with Myelomeningocele

Given the complexity of MMC, some have thought it more merciful to withhold treatment and allow these infants to die. In 1971, Lorber developed criteria to select infants for nontreatment; these included severe hydrocephalus at birth, total paraplegia, spinal kyphosis, and an additional birth defect.⁸⁹ In 2001, the Groningen Protocol was developed in the Netherlands to select infants for active euthanasia who were thought to be in “unbearable suffering” and to have a “hopeless prognosis”; 22 infants were euthanized by lethal injection as of 2010.

However, none of these criteria, either in isolation or in combination, are entirely accurate predictors of outcome,⁹⁰ and in the United States, most children are treated. In a landmark study by McLone, the outcome of nonselective treatment

compared favorably with that in the selected series of Lorber.⁹¹ Parents of children with MMC in the United States rarely regret a decision to treat their child, with only 4 of 300 regretting their decision to treat and 9 regretting their initial decision not to treat.⁹⁰ Withholding treatment may rarely be considered for children with other, potentially fatal congenital malformations or chromosomal abnormalities, but this decision should be individualized and made only after a frank and realistic discussion with parents.

Neurosurgical care for the child with MMC can be divided into three phases: (1) initial stabilization of the infant and closure of the MMC; (2) assessment and treatment of associated hydrocephalus when present; and (3) long-term management of associated shunt malfunctions, the Chiari malformation, tethered spinal cord, and syringomyelia.

24.3.1 Stabilizing the Infant and Closing the Myelomeningocele

The MMC contains potentially functional tissue, so it should be protected from external mechanical trauma and desiccation and kept as clean as possible. Sterile saline-soaked gauze dressings and plastic wrap keep the malformation moist; iodine-containing compounds should be avoided as they may injure exposed tissues. Prophylactic antibiotics (usually ampicillin and gentamicin) are usually administered for the first 3 days.

The initial newborn evaluation should focus on several aspects. A general physical examination may disclose evidence of a more widespread genetic or developmental syndrome. Sensorimotor function is assessed by observing spontaneous leg movements and the response to pinprick stimulation (► Table 24.1). Muscle imbalance yields characteristic leg postures, such as hip flexion for upper lumbar level lesions, knee extension for midlumbar lesions, and ankle dorsiflexion with low lumbar level lesions. Clinical signs of hydrocephalus include accelerated head growth, full fontanel, split cranial sutures, and limitation of upgaze/“setting sun” eyes. Brainstem signs include bradycardia, apnea, dysfunctional swallow, high-pitched or weak cry, vocal cord palsies, and hypotonia. Severe brainstem dysfunction on the first day of life is a particularly ominous sign, especially if it persists after ventricular shunting.

The MMC may be repaired within the first 3 days without an increased complication risk.⁹² The placode is sharply dissected from the surrounding skin at the perimeter of the malformation

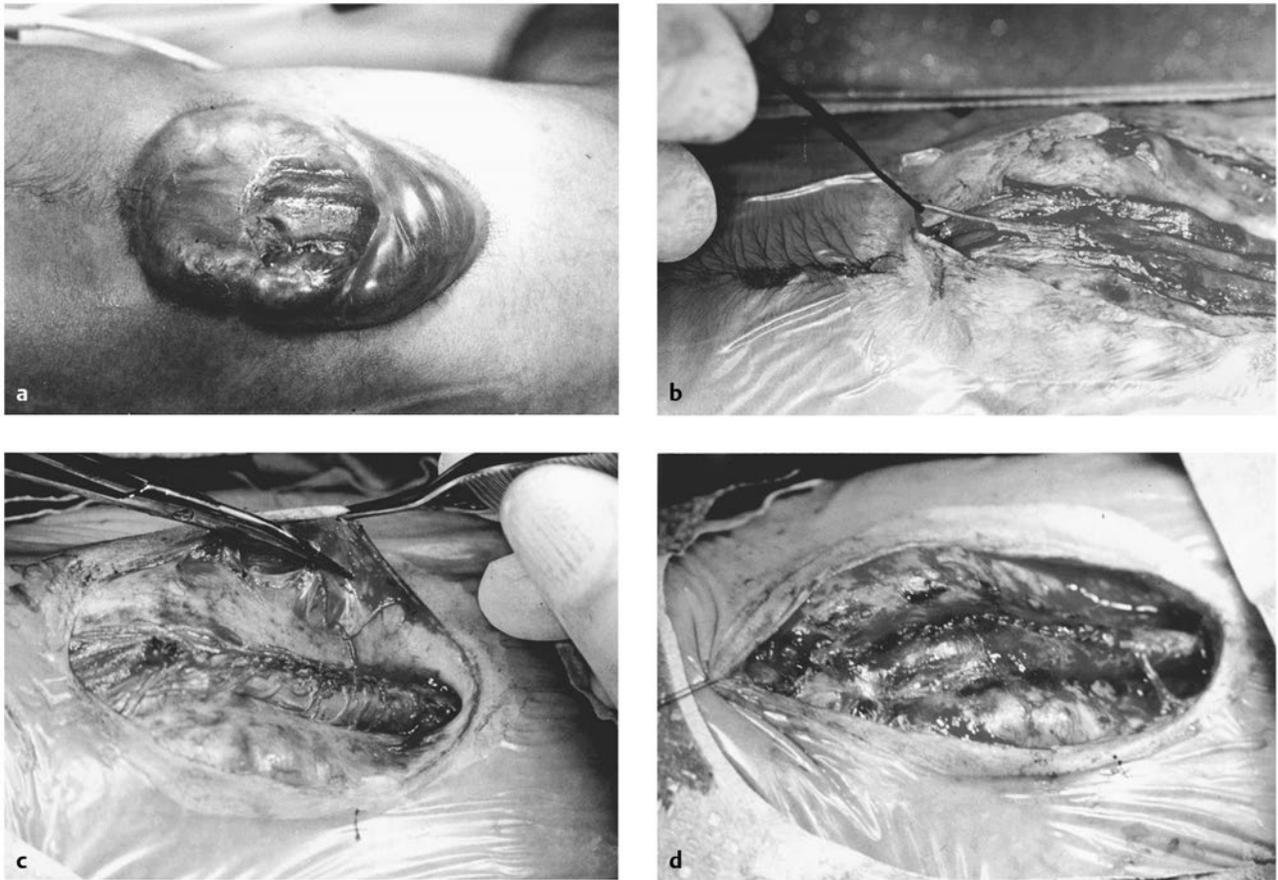

Fig. 24.3 Closure of myelomeningocele. (a) Myelomeningocele sac on dorsum of newborn infant. Placode is in the center and attached circumferentially to the adjacent dysplastic skin. (b) The placode has been dissected circumferentially from the skin and rolled up to re-create a neural tube. In this case, there is an intact filum terminale caudal to the placode, which will be sectioned. (c) The dura is dissected from under the skin circumferentially and brought together to cover the newly “closed” placode. (d) The dura is closed with running suture. The skin is undermined just above the lumbodorsal fascia and brought together in the midline with as little tension as possible. Another layer may be added by elevating the muscles and fascia on either side of the splayed posterior elements and bringing them together over the closed dura before skin closure.

(► Fig. 24.3a), avoiding injury to subjacent nerve roots. Skin tissue is meticulously dissected from the placode to avoid a subsequent inclusion dermoid.^{93,94} Small feeding arteries and draining veins are spared if possible. The lateral edges of the placode are approximated with the use of fine suture to reconstitute the neural tube (► Fig. 24.3c), which may make subsequent untethering easier to perform. Some surgeons excise the placode in patients with thoracic or thoracolumbar lesions and no leg function to facilitate dural closure and reduce the risk for subsequent retethering, but urologic worsening may occur in 8%.^{95,96}

Any other tethering malformation, such as a lipoma, split-cord malformation, or filum terminale, should be untethered if present (► Fig. 24.3b). One important variant, a *hemimyelomeningocele*, is suggested preoperatively by a significantly asymmetric motor examination and a sac that is slightly off midline. A hemimyelomeningocele is a form of split-cord malformation in which the spinal cord splits into two “hemicords,” one of which is exposed on the surface while the other is hidden under, and separated from, the exposed hemicord within its own separate dural sac.⁹⁷

Once the placode is closed and all related tethering malformations treated, the surrounding dura is then circumferentially elevated from the underlying fascia (► Fig. 24.3c), and the dural sac is reconstituted with enough space to avoid strangulating the placode (► Fig. 24.3d). Dural grafts are rarely necessary, do not appear to decrease the risk for subsequent tethering, and may increase the risk for CSF leak.

The lumbodorsal fascia may be closed as an additional layer, but the benefits are unclear as cerebrospinal fluid (CSF) leaks occur in only 1 to 3% overall.⁹⁸ One study found no additional benefit to myofascial closure,⁵⁴ whereas a second study reported that CSF leakage and shunting were less frequent.⁹⁹ Periosteal “turnover flaps” with the use of lumbodorsal fascia and acellular dermal matrix are also reported.^{100,101}

Finally, the redundant skin is trimmed and closed. Vertical, horizontal, and Z-plasty closure techniques¹⁰² have been described, although a simple vertical closure is preferred because it simplifies later spine procedures should they become necessary. The skin is undermined circumferentially above the lumbodorsal fascia with sharp dissection; small perforating vessels

arising from the fascia should be avoided if possible to prevent flap ischemia. As the skin edges are drawn together, some temporarily blanching often occurs but is usually transient; topical nitroglycerin paste may improve skin blood flow. Excess dysplastic skin is trimmed, and the normal skin is closed in a layered fashion.

Large skin defects may require rotational or myocutaneous flaps that are beyond the scope of this chapter and are reviewed elsewhere.¹⁰³ Wound complication rates are lower following flap closure in some studies,^{104,105} but not others.¹⁰⁶ In a novel technique (Ken Winston, personal communication, 1997), Silastic sheeting (used for creating silos for gastroschisis) is sewn circumferentially to the underside of the elevated skin flaps well back from the skin edges. The Silastic sheet is then plicated by drawing up the center of the sheet and suturing it every

other day on the ward to progressively pull the flaps together; once the skin is overlapping, the Silastic sheet is removed and the wound closed primarily (► Fig. 24.4a,b). A similar progressive purse string cerclage technique has also been reported.¹⁰⁷

Severe kyphosis complicates about 12% of cases of MMC.¹⁰⁸ Although most patients are paraplegic, a few have some preserved sensorimotor function. Kyphosis can lead to difficulty with the initial MMC closure, subsequent skin breakdown or ulceration, sitting imbalance, pulmonary restriction, and loss of neurologic function. Kyphectomy at the time of initial closure has been recommended because kyphosis commonly progresses, and later correction is risky. Kyphectomy in infancy significantly decreases recurrence, particularly if the lordotic curvature is restored.¹⁰⁹ The placode is excised and the superior dura imbricated, or the placode and thecal sac are displaced

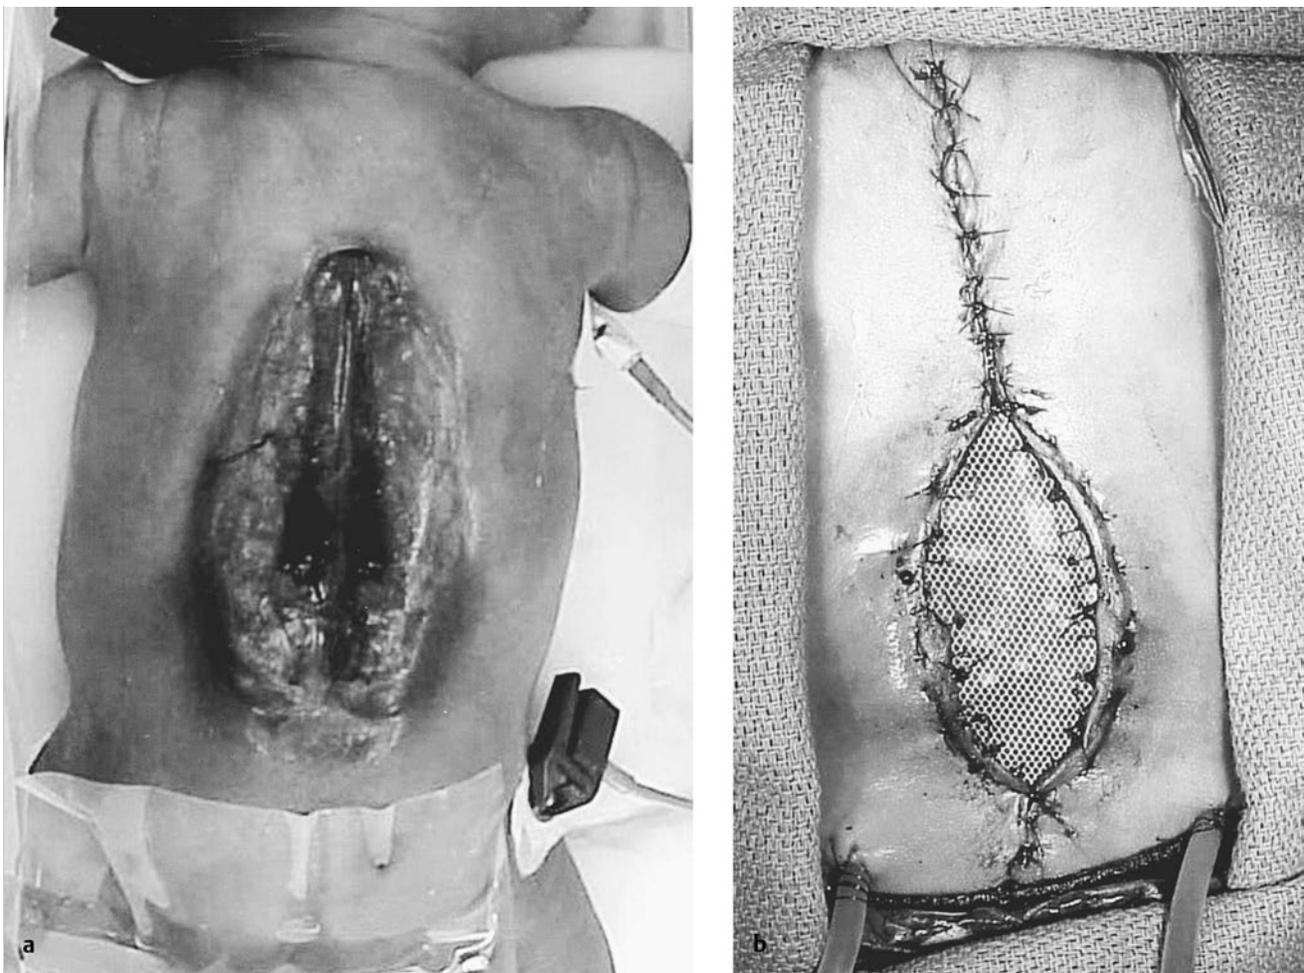

Fig. 24.4 Closure of large myelomeningocele by the progressive approximation of Silastic sheeting. (a) Huge thoracolumbar myelomeningocele. (b) Much of the myelomeningocele has been closed primarily, but the portion that remains open is attached along its undersurface to Silastic sheeting. This sheeting is plicated in the midline every few days in the neonatal intensive care unit, with the skin edges drawn progressively closer until they overlap. The child is then returned to the operating room, the Silastic sheet is removed, and the skin is closed primarily.

laterally to expose the underlying vertebra(e) at the apex of the kyphos. Laterally displaced laminae and pedicles are removed with rongeurs. The vertebral bodies and adjacent disks at the apex of the kyphotic deformity are removed piecemeal with rongeurs and/or a high-speed drill, with extreme care taken to avoid injury to the subjacent vascular and retroperitoneal structures. Hemostasis is meticulous, but a transfusion should be anticipated. The kyphos is reduced by extending the femora under the drapes and bringing the adjacent end plates together; the newly approximated vertebrae are sutured together with several heavy (No. 1 or No. 2) nonabsorbable sutures supplemented with the excised bone chips.¹⁰⁹ A body cast or custom orthosis is worn for 12 weeks.

24.3.2 Initial Treatment of Hydrocephalus

Hydrocephalus occurs in 80 to 90% of children with MMC,^{58,110} and 70 to 90% undergo shunting.^{56,111} For infants with overt signs of hydrocephalus at birth, MMC closure and contemporaneous shunting may be performed with no apparent increased risk and perhaps decreased wound leakage.^{112–114} External ventricular drainage or a ventricular reservoir may be used to temporize, particularly for those infants whose MMC was repaired more than 72 hours after delivery, in whom contemporaneous shunting is associated with a higher infection rate.¹¹⁵

For those with modest ventricular enlargement and no clinical evidence of hydrocephalus, neither absolute criteria nor consensus is available about when to place a shunt. One study suggested that infants with a cortical mantle thickness of 2.8 cm or larger may not need shunting.¹¹⁶ Various measurements, such as the Evans ratio or the average of the maximum frontal and occipital horn widths divided by the distance between the cortical surfaces,¹¹⁷ have been proposed but are rarely used in decision making. There is significant variability among pediatric neurosurgeons regarding the threshold for shunt placement in asymptomatic children with ventriculomegaly,¹¹⁸ likely related to uncertainty about the effects of moderate ventriculomegaly on brain development compared with the risks of shunt revisions and infections. Many pediatric neurosurgeons prefer moderate ventriculomegaly to ongoing and repeated shunt complications.¹¹⁸ On the other hand, cognitive improvements may occur even when a shunt is placed years later.¹¹⁹

24.3.3 Long-term Neurosurgical Management of Children with Myelomeningocele

Children with MMC are best managed in the setting of a multidisciplinary clinic specializing in the treatment of spina bifida, where pediatric surgical specialists, therapists, and a nurse coordinator are available¹²⁰; the clinic can be an integral part of the medical home for these children.¹²¹ Pediatric neurosurgical care focuses on four major issues: the shunt, the Chiari malformation, syringomyelia, and spinal cord tethering. Management follows seven basic principles:

1. Each child has a unique set of *static* neurologic, orthopedic, and urologic deficits.

2. Each child has a set of radiographic abnormalities, including hydrocephalus in 70 to 80%, Chiari malformation in more than 95%, syringomyelia in 40 to 80%, and tethering in virtually 100%.
3. *The mere presence of a radiographic abnormality, or even a radiographic change, does not necessarily direct treatment. Rather, treatment should generally be reserved for clinical deterioration.*
4. *Any neurologic, urologic, or orthopedic deterioration* should prompt a search for a treatable cause.
5. *Any clinical deterioration* can potentially be caused by shunt malfunction, and all evaluations should therefore begin by excluding *shunt malfunction*.
6. If available, ventricular size at the time of suspected shunt malfunction *must be compared with a baseline*. Moreover, a shunt malfunction may occur with *little or no change in ventricular size*. An open mind is required.
7. Papilledema may occasionally develop with few or no symptoms; a *funduscopy examination* should be performed once the child is able to cooperate.

Shunt Management in Children with Hydrocephalus

The signs and symptoms of shunt malfunction in the child with an MMC are legion. The usual symptoms and signs—headache, nausea and vomiting, poor feeding, listlessness or lethargy, setting sun eyes, and extraocular abduction palsies—are not universal. Symptoms may be subtle or intermittent in nature, and of course not every headache is shunt-related. Experienced parents may be able to tell whether or not their child's symptoms suggest shunt malfunction¹²²; be wary of dismissing an experienced parent's concerns! Other patterns of shunt malfunction include the following:

- Cognitive changes such as a decline in school performance or worsening behavior
- New onset of seizures or change in the pattern of seizures without another cause
- Decreased arm or leg strength, loss of previously acquired motor skills, or increased tone
- Unexplained change in ambulation
- Worsening urinary and/or bowel function
- Neck pain, lower cranial nerve or brainstem dysfunction.
- Pain at the MMC closure site
- Progressive scoliosis or orthopedic deformities

Any deterioration should first prompt a thorough investigation of shunt function before any other neurosurgical treatment is undertaken, especially if there are any associated headaches or cognitive changes.

Most children have increased ventricular size on computed tomography (CT) compared with their baseline. A shunt series may reveal disconnected or broken tubing. Notably, shunt pumping is of no demonstrated value.^{123,124} Other adjunctive measures may include a shunt tap, radionuclide study, or continuous intracranial pressure (ICP) monitoring. A shunt tap may be helpful if it demonstrates (1) sluggish or absent proximal flow (suggesting a proximal occlusion), (2) brisk flow and high pressure with manometry (suggesting a distal occlusion), or (3) proximate relief of headaches after fluid removal. Radionuclide

shunt studies involve injecting tracer through the shunt into the ventricles while occluding distal outflow. Over time, the tracer should flow distally; failure to do so suggests malfunction. ICP monitoring is helpful if it demonstrates an acute rise in ICP concurrent with headaches. Unfortunately, shunt taps, radionuclide studies, and ICP monitoring are *least* reliable with a partially occluded shunt, and no test can absolutely exclude a shunt malfunction. Ultimately, the diagnosis rests on the *clinical condition of the child*, and a shunt exploration may be needed if symptoms continue. This cannot be overemphasized—nowhere else in pediatric neurosurgery is clinical judgment so important, and misjudgment so treacherous.

Endoscopic third ventriculostomy (ETV) has emerged as an alternative to shunt revision with overall success rates of higher than 70% among eligible patients with MMC and (1) evidence of noncommunicating hydrocephalus by CT ventriculography and/or MR imaging, (2) minimal or no discernible subarachnoid space, and (3) a third ventricle at least 4 mm wide.¹²⁵ The success rates are lower in children younger than 6 months than in older children.¹²⁵ ETV is technically more challenging and difficult in this population because of abnormal third ventricular anatomy, distorted foramina of Monro, and interthalamic adhesions. A combination of ETV and choroid plexus cauterization (ETV/CPC) was more successful (76%) among infants with MMC in sub-Saharan Africa than was ETV alone (35%), with comparable intellectual outcomes and fewer later failures.^{126,127} Whether these results can be reproduced remains to be seen.

Can a child with MMC and hydrocephalus managed with a shunt ever be considered shunt-independent? There are certainly anecdotes of shunt disconnections or breaks seen incidentally on radiographs in asymptomatic patients. However, abrupt or even fatal deterioration has been reported months or years later.^{128–130} A radionuclide study may confirm that CSF is not flowing through the intervening shunt tract,¹³¹ but the validity of this technique has not been evaluated in patients with MMC. The difficulty in determining shunt independence with certainty, and the possibility of sudden decompensation, should be carefully discussed if observation is chosen.

Management of the Chiari Malformation

The Chiari 2 malformation is a pancerebral abnormality (see box “Chiari-Associated Central Nervous System Malformations”) that is present in most children with MMC. Herniation of the cerebellar vermis, brainstem, and fourth ventricle through the foramen magnum may cause lower brainstem signs and symptoms, although most children are relatively asymptomatic and fewer than one-third require surgery.^{58,91,132–137} Presenting symptoms are most frequent during the first year, with lower cranial neuropathies, swallowing dysfunction, and disordered breathing predominating.¹³² Almost all children with MMC have modest swallowing issues, such as a hyperactive gag reflex, intolerance for particular food textures, gagging (usually on solids), and more frequent vomiting, all of which usually improve over time and do not require treatment. More concerning are *progressive* swallowing abnormalities, such as choking on liquids, significant weight loss, nasal regurgitation, and aspiration pneumonia. Other concerning signs may include those of disordered breathing: central or obstructive apnea, cyanotic spells (sometimes even when the child is on a ventilator¹³³),

inspiratory stridor, and a hoarse, weak, or high-pitched cry. Stridor and apnea at delivery are more ominous and have a higher mortality rate and poorer outcome than stridor and apnea that develop later.¹³⁸ Vocal cord palsies, particularly when bilateral, are often irreversible and require tracheostomy.¹³⁹ Other signs and symptoms (particularly in the older child) may include weakness and/or spasticity of the upper extremities, pain (headache and/or neck pain), cerebellar problems, oculomotor dysfunction, and scoliosis.^{42,132,139,140}

The Chiari 2 malformation is well seen on sagittal T1 or T2 MR images (► Fig. 24.5). A speech and swallow evaluation may disclose phonation difficulties, hoarseness, or abnormal swallow. A formal swallowing study¹³² may disclose disordered swallowing mechanics, incomplete clearing or pooling of tracer in the vallecula, occult tracheal aspiration, or reflux. Radionuclide swallow studies may also reveal occult aspiration. Direct laryngoscopy may disclose unilateral or bilateral vocal cord weakness, and pulmonary studies may demonstrate episodic central or obstructive apnea.

Whether to treat the Chiari malformation depends upon the age of the patient and the severity and progression of clinical signs. Mild, nonprogressive swallowing issues usually improve without treatment. Newborns with apnea, bilateral vocal cord palsies, absent gag or swallowing function, and hypotonia do poorly despite treatment^{138–140} and may have an anatomically disordered brainstem.¹⁴¹ Some argue that Chiari decompression in infants is futile because the high case mortality rate with surgical treatment in infants is no better than the natural history.^{135,142} Others have reported significantly better outcomes in symptomatic newborns who are treated early and aggressively.^{139,140,143} Two studies of symptomatic neonates who underwent early surgery demonstrated significant improvement in 61 to 77%, with better outcomes following earlier treatment but an overall case mortality of 23%.^{139,140} There appears to be little consensus regarding the most appropriate treatment.¹⁴⁴ Older children with symptomatic Chiari 2 malformations have much better postoperative outcomes, although surgery for this population has declined significantly with the realization that most of these patients have an underlying shunt malfunction. The first approach to treating a symptomatic Chiari malformation at any age is to exclude hydrocephalus and/or shunt malfunction, and a shunt insertion or revision should be strongly considered before a Chiari decompression is undertaken.

Chiari decompression involves a cervical laminectomy to the lowest level of the cerebellar tonsils (not to the medullary kink) and duraplasty with autologous tissue or allograft. The foramen magnum is usually large, and occipital bony decompression and posterior fossa dural opening are rarely necessary, entail a greater risk for hemorrhage from intradural venous lakes and pathologically low venous sinuses, and may not improve outcomes. Other procedures, such as opening and/or stenting the fourth ventricle¹⁴⁵ and plugging the obex,^{146–148} are of no proven additional benefit and add considerable surgical risk resulting from dissection through the scarred vermis. Significant syringobulbia may require opening the fourth ventricle and draining the brainstem cyst.

Complications of Chiari decompression are age-related, with the highest mortality rate in infants.^{139,140} Bleeding from dural venous lakes, low-lying transverse sinuses, or the torcular may

(a) Midsagittal T1-weighted magnetic resonance (MR) image shows disordered sulcation of the posterior cortex (stenogyria), dysgenesis of the corpus callosum, beaked tectum, and enlarged massa intermedia of the thalamus. be frighteningly significant, and the sagittal MR image should be scrutinized preoperatively. Direct brainstem trauma, vascular injuries, CSF leaks, and wound and shunt infections are rare. Delayed post-laminectomy kyphosis is unusual, although one study reported a 40% incidence.¹⁴⁹

The outcome depends upon the age and mode of presentation. Newborns with bilateral vocal cord palsies and apnea often require tracheostomy, gastrostomy, and Nissen fundoplication. Neonates with less severe brainstem involvement and at least one functioning vocal cord¹³⁹ and older children fare better.

Management of the Tethered Spinal Cord

Neurologic deterioration usually has a cause and is not the “natural history of MMC.” Tethering is a well-recognized cause of deterioration in this population,^{150–157} with one-third requiring untethering in childhood.¹⁵⁴ The pathophysiology of tethering reflects physical spinal cord stretching that leads to decreased spinal cord blood flow, a shift to anaerobic metabolism, reduced glucose metabolism, and mitochondrial failure.^{158,159} Vertebral column growth progressively stretches the spinal cord; the incidence of symptomatic tethering increases during periods of

rapid growth.^{151,160–162} Repetitive traction on an already tethered spinal cord with flexion movements of the pelvis and/or spine may exacerbate the problem.¹⁶³ Several studies have documented stabilized or improved neurologic function,^{151,155,160,164–166} urologic function,¹⁵² and orthopedic deformities^{153,156,157} after untethering.

Because every patient with MMC is radiographically tethered (► Fig. 24.6), the decision to untether the spinal cord in this population is based solely upon *clinical grounds*. The position of the conus medullaris does not change appreciably after tethered cord release, even though patients improve clinically.¹⁶⁷ A vigilant eye, keen clinical judgment, and objective, accurate, and reproducible adjuncts, such as serial manual muscle testing, urodynamics, and scoliosis X-rays, are needed to properly evaluate the child for tethering.

Signs and symptoms of spinal cord tethering may include the following:

- Pain in either the back or legs
- Motor deterioration—decreased muscle strength and/or increased tone (spasticity)
- Sensory worsening

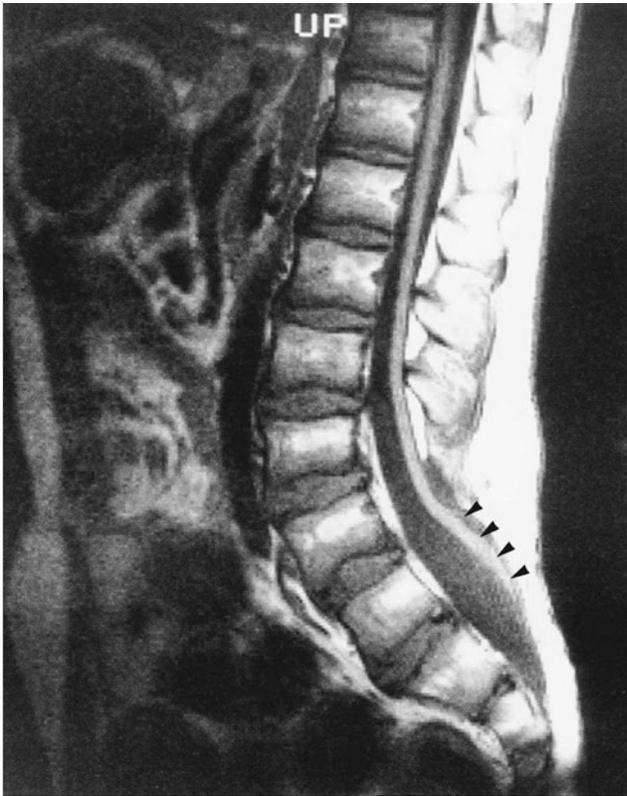

Fig. 24.6 Tethered spinal cord. Midsagittal T1-weighted magnetic resonance image showing the spinal cord ending dorsally at the level of the L4–S1 vertebral bodies (arrowheads).

- Worsening bowel and bladder function
- Deteriorating gait
- Progressive orthopedic deformities of the legs (hip dislocation, pes cavus, equinovarus) or spine (scoliosis)

Pain is common but seldom the only complaint. Pain in the back and/or legs is usually ill-defined, dull, and achy in character, and it may extend even into areas that are insensate. Leg pain may have a dysesthetic or neuropathic quality and be exacerbated by exercise or effort. Fortunately, pain is almost universally relieved after untethering procedures.

Sensorimotor changes are the most frequent presentation¹⁶⁸ and include declining muscle strength, increased tone (spasticity), deteriorating gait, and sensory loss. Manual muscle testing, performed serially by trained physical therapists at least yearly, provides a *quantifiable and reliable assessment of motor function with interobserver reliability*. A consistent decrease of at least one grade in several muscles is significant. Muscles innervated by the “last intact root,” with ascending weakness, or patchy muscle weakness in multiple muscles innervated by more rostral spinal levels may develop. Spasticity, hyperreflexia and/or clonus, progressive muscle contractures, and/or deteriorating gait may be present. Gait deterioration from tethering is the result of progressive muscle weakness, increasing spasticity, or orthopedic deformities; a progressive “sagging” gait due to hamstring or iliopsoas contractures is a common presentation. Subjective sensory complaints are relatively common, although objective

sensory changes are usually accompanied by other signs of neurologic deterioration.

Patients who have urologic deterioration may present with incontinence between catheterizations, an increase in the frequency of catheterizations, or more frequent urinary tract infections without another cause. If found, bladder infections should be treated before the urologic changes are ascribed to tethering. Bladder function is objectively assessed with serial urodynamic testing.^{72,169} A progressively smaller bladder capacity and/or increased bladder pressures, reduced thresholds for initiating bladder contractions (uninhibited bladder contractions), and bladder contractions against a closed urethral sphincter (detrusor–sphincter dyssynergia) are all potential signs of tethering. Bladders with high intraluminal pressures (>40 cm H₂O) and those with uninhibited contractions or dyssynergia increase the risk to the upper urinary tract. Urologic improvement occurs in approximately 60% of patients after untethering.¹⁵² Less common abnormalities of defecation may also improve after untethering.¹⁵²

Orthopedic deformities are common and their etiology is multifactorial, but tethering may contribute to progressive orthopedic deformities, including hip subluxation, pes cavus, and equinovarus deformities. Associated weakness, bladder dysfunction, or pain may provide additional evidence. For those with only orthopedic deformities, untethering may be performed initially in the hope of reversing the orthopedic deformity, or the underlying orthopedic deformity may be corrected and untethering reserved for those with recurring deformities. No studies have directly compared the outcomes of these two approaches.

Finally, scoliosis occurs in up to 90% of children with MMC^{170, 171} and is more frequent among those with thoracic and upper lumbar lesions.¹⁵⁶ Scoliosis is multifactorial and the result of paravertebral muscle weakness and sensorimotor imbalance, vertebral malformations such as hemivertebrae and segmental bars, pelvic obliquity or hip contractures, and/or neurosurgical conditions (Chiari malformation, syringomyelia, and spinal cord tethering).^{156,170} The *frequency* of scoliosis increases with both higher-level lesions and *older* age, whereas the *progression* of scoliosis (once present) correlates with a higher degree of curvature, *younger* age, and nonambulatory status. Scoliosis may be stabilized or reversed with untethering, particularly in those with midlumbar-level lesions and initial curves of less than 45 degrees; low-lumbar and sacral lesions are also likely to benefit, although the low incidence of scoliosis in this group precludes a meaningful analysis. In contrast, there appears to be little benefit to untethering for high-lumbar and thoracic lesions and for those with curves of more than 45 to 55 degrees. Although there is a fear that corrective scoliosis surgery without a prior “prophylactic” untethering will result in neurologic worsening from tethering or the Chiari malformation, there is no evidence to support this.¹⁷² Among 17 patients who underwent scoliosis correction (average improvement of 47 degrees) without prior untethering, none had neurologic deterioration or shunt malfunction.¹⁷³

Once again, the evaluation of tethering always begins with an assessment of shunt function. A malfunctioning shunt should be revised and the child reassessed several weeks postoperatively; if there is no clinical improvement, tethering is then considered. Adjuncts to evaluation include manual muscle testing,

urodynamic studies, and/or scoliosis radiographs. MR imaging of the entire spinal cord confirms tethering radiographically; identifies associated lesions such as lipomas, split-cord malformations, hydromyelia, and spinal stenosis, which may contribute to neurologic deterioration; and provides important surgical landmarks. However, *radiographic* signs of tethering alone do not determine the need for surgery in the absence of *clinical* deterioration.

Untethering involves reopening the previous closure and extending it slightly cranially to identify the last formed spinal segment (which can be removed if necessary to expose normal dura). The exposed dura is opened in a cranial to caudal direction; the surgeon works from normal spinal cord toward the placode and dissects the scarred placode and nerve roots from the dura. If possible, dissecting between the dura and arachnoid minimizes injury to the dorsolaterally adherent nerve roots. Other tethering lesions (lipomas, filum terminale, midline bands from split-cord malformations) are also untethered. Occasionally, the placode is so scarred that complete untethering is impossible; the goal is to untether as much as is safely possible. For children with no functional leg movements, some surgeons amputate the placode (the ultimate untethering). However, urologic deterioration occurs in 8%,^{95,96} and we therefore do not recommend this. Once untethering is complete, a primary dural closure is usually adequate; dural grafts are rarely necessary and do not appear to decrease retethering rates.

Complications are uncommon; neurologic or urologic worsening occurs in 3 to 5%. Postoperative symptomatic pseudomeningoceles or CSF leaks are infrequent and if present should suggest an occult shunt malfunction. Long-term outcomes are good.¹⁶⁸ In one study, pain improved in nearly 100%; weakness improved in 70%, stabilized in 28%, and deteriorated in 2%; spasticity improved in 63% and stabilized in 37%; gait improved in 79%, stabilized in 19%, and worsened in 3%; and bladder function improved in 67%, stabilized in 30%, and deteriorated in 3%. A second untethering was required in about 30% of those undergoing a tethered cord release. Of those requiring a second untethering, 39% required a third, and of these, 13% required a fourth release.¹⁶⁸ Although the mechanism is unclear, signs and symptoms characteristically ascribed to the Chiari 2 malformation may also improve after untethering, including nystagmus (66%), headache (69%), and upper extremity sensory loss (100%), although none resolved completely.¹⁷⁴

Management of Hydrosyringomyelia

Hydrosyringomyelia is present in 50 to 80% of patients with MMC^{67,175,176} but is symptomatic in only about 1.8 to 5%.¹⁷⁷ Again, *clinical deterioration* directs management, and clinical judgment is critical in selecting patients for treatment because

symptoms and signs may overlap those from spinal cord tethering and Chiari malformation. Clinical features may include upper extremity weakness, loss of function, and/or deformities (claw hand); neck or back pain; scoliosis; ascending motor loss; or increasing leg spasticity. The classic cape distribution “dissociated sensory loss” (loss of pain and/or thermal sensation with preserved light touch and proprioception)¹⁷⁸ is uncommon in our experience. Brainstem extension (syringobulbia) may produce brainstem dysfunction. Changes in urinary function are rare and should suggest spinal cord tethering.¹⁷⁸ Scoliosis due to hydrosyringomyelia is often rapidly progressive and thought to result from asymmetric anterior motor column damage.^{179–181}

Small or moderate-size hydrosyringomyelia cavities that are asymptomatic do not require treatment because the risks outweigh the benefits. Symptomatic hydrosyringomyelia may also reflect an underlying shunt malfunction.^{179,182} Treatment for symptomatic hydrosyringomyelia is controversial. Surgical options include Chiari decompression, syringo-subarachnoid stent, syringoperitoneal or syringopleural shunt, myelotomy, and tethered cord release.¹⁷⁷ Unfortunately, the literature is limited to case reports and retrospective series with only short-term radiologic or clinical success in some patients following all of the various treatments. Sklar and Shapiro analyzed outcomes of various treatments in 50 patients with MMC and hydrosyringomyelia. Posterior fossa decompression was successful (syrinx unchanged or decreased) in only 14% of patients, whereas syringo-subarachnoid stenting was successful in 70%. A combination of the two was successful in both children in whom it was performed. No syringoperitoneal or syringopleural shunts were performed in this series.¹⁸³

La Marca et al proposed a management algorithm (► Fig. 24.7) that divided hydrosyringomyelia into segmental (involving only a segment of spinal cord) and holocord (involving the entire spinal cord) types. Each type was further subdivided into mild, moderate, and severe forms; treatment in this series was reserved for those with moderate or severe forms. Finally, they described three groups based on clinical presentation: group 1, with predominantly Chiari-like symptoms (neck pain, stridor or vocal paresis, swallowing difficulties, or arm symptoms); group 2, with predominantly tethering-like symptoms (back pain, scoliosis, sensorimotor changes in the legs, or bowel and bladder changes); and group 3, with mixed symptoms. Treatment was determined by both the anatomical type and the presenting clinical symptom complex: group 1 patients with either a holocord or segmental syrinx underwent Chiari decompression, whereas group 2 patients with either a holocord or segmental syrinx and group 3 patients with a segmental syrinx underwent an untethering procedure. Only group 3 patients with a holocord syrinx underwent a syrinx shunt. When

this algorithm was applied retrospectively to 45 patients, it led to better clinical and radiologic outcomes and fewer complications than were seen in those for whom the algorithm had not been followed.¹⁸⁴ Piatt, in a critical review of the existing literature,¹⁷⁷ concluded that the lack of class 1 or class 2 data precludes any firm treatment recommendations and suggested a multi-institutional cohort study using an algorithmic approach such as that proposed by La Marca et al.

24.4 Summary

The single greatest long-term neurosurgical problem for children with MMC remains the maintenance of proper shunt function. Every year, several children die as a result of unrecognized shunt malfunction; many of these deaths could be prevented if shunt malfunction were promptly recognized and dealt with. Understanding that the signs and symptoms of shunt malfunction in this population are legion and may not be associated with a change in ventricular size on CT scans will advance the care of these children considerably.

We reject the concept that delayed deterioration is simply the “natural history” of MMC; the cause of neurologic decline is eminently treatable in many cases. Aggressive treatment of associated neurosurgical disorders such as the Chiari malformation, hydrosyringomyelia, and spinal cord tethering has resulted in improved ambulation, better urinary function, and fewer orthopedic deformities; it has also obviated, in many cases, the need for spinal fusion and soft tissue releases for scoliosis and lower limb spasticity, respectively. With further advances, the outlook for these children remains ever more hopeful.

Pearls

1. Deterioration is not the natural history of MMC and has a potentially treatable cause. Any work-up for clinical deterioration should begin with a consideration of shunt malfunction.
2. Shunt malfunction may occur without a change in ventricular size. Imaging that shows normal ventricular size, or no change in size compared with baseline, may not be sufficient to exclude a shunt malfunction, particularly if any signs or symptoms (headaches, emesis, seizures, deterioration in cognitive function or personality) suggest a shunt malfunction as the root cause for the deterioration.
3. Mild or moderate stable swallowing issues are common in early childhood and often improve over time as the child ages. Chiari decompression should be reserved for those having significant swallowing issues (tracheal aspiration, emesis with inability to maintain weight) or associated vocal cord weakness, stridor, or apnea, and it should be undertaken with extreme caution. Beyond infancy, Chiari symptoms are almost always due to occult shunt malfunction.
4. Once shunt malfunction has been excluded, neurologic deterioration is most commonly due to spinal cord tethering, and a tethered cord release is the best treatment option. Syringomyelia is common in children with MMC but is rarely symptomatic.

25 Occult Spinal Dysraphism

D. D. Cochrane

The term *occult spinal dysraphism*¹ (OSD) refers to a group of disorders arising as a result of the malformation of midline dorsal neural, mesenchymal, and cutaneous ectodermal structures during embryogenesis. OSD was originally grouped by von Recklinghausen² with spina bifida aperta because they share defective lamination of the posterior arches and present as abnormalities of skin, fat, laminae, and neural tissue. Over the past two centuries, OSD has come to encompass diastematomyelia and split-cord malformation (SCM), meningocele manqué, dermal tract or sinus with and without intraspinal tumors, lipoma of the conus and/or filum, and other abnormalities of the filum.^{3,4}

Although these conditions vary in their clinical features, embryopathology, and response to treatment, the clinical disorders that are categorized as OSD have four features in common: (1) The major causes of neurologic impairment in these patients are spinal cord tethering, neural compression, and myelodysplasia; (2) when no surgical treatment is instituted, patients may develop progressive neurologic deficits as a result of cord tethering, trauma, or compression; (3) progressive and evolving deficits are amenable to surgical intervention, whereas static deficits are not⁵⁻⁸; and (4) anatomical and postoperative clinical retethering occurs and requires that these patients be monitored for neurologic, urologic, and orthopedic deterioration, even after a successful operation.^{5,9}

The clinical features that characterize OSD have been the subject of interest through the ages. The “faun’s tail” that commonly accompanies diastematomyelia, the pes cavus, and the calf atrophy may have been the genesis of the satyr of Greek mythology.² Descriptions of SCMs, including the introduction of the term *diastematomyelia* with and without bony septum and fibrous bands, “all associated with greater or lesser degrees of spina bifida,” appeared in the late 19th century.¹⁰ The surgical significance of SCM had to await the reports of Marr and Uihlien 1944,¹¹ and of Matson et al in 1950.¹² The importance of congenital lipomas of the conus and filum was initially brought to attention by Bassett in 1950 in a report of patients who had lipomas of the conus and filum, presented with urinary incontinence due to neurogenic bladder, and recovered continence postoperatively. Walker and Bucy¹³ were the first to recognize the association between congenital dermal sinus, meningitis, and paralysis. Tethering of the spinal cord by the filum terminale as a cause of neurologic deterioration was a concept suspected by Garceau.¹⁴ Hoffman et al¹⁵ introduced the term *tethered cord syndrome* to refer to this entity. Subsequently, its use was expanded to include restricted cord movement with any and all etiologies.¹⁶

25.1 Epidemiology

The incidence of OSD in the general population is not known. Unlike the diagnosis of open defects, which are clinically obvious, that of closed defects requires awareness of the significance of cutaneous markers and often subtle neurologic deficits and musculoskeletal deformity. There is little information

regarding the risk factors predisposing to nonsyndromic closed spinal dysraphic states. The observation that open and closed neural tube defects may be genetically related¹⁷ suggests that at least some risk factors may apply to both types of spinal malformations. Studying 364 siblings of 207 patients with all forms of OSD, Carter et al found a 4% incidence of myelomeningocele or anencephaly in the series. Patients with OSD and families with caudal regression syndrome may share risk factors, in particular, maternal diabetes.^{18,19}

The incidence of anomalies associated with cord tethering, including imperforate anus, have been shown to decrease with the periconceptual consumption of folic acid.²⁰ However, dietary folic acid supplementation has not been shown to decrease the incidence of lipomyelomeningocele in Nova Scotia.²¹

25.2 Pathology and Pathogenesis

25.2.1 Intradural Lesions

Tight Filum Terminale

An abnormally tight filum terminale causes caudal traction on the spinal cord.^{4,14,15} The diagnosis is suspected on clinical grounds and confirmed when the conus position is abnormally low, or is in a normal position (above L2),^{15,22,23} by the presence of fat in the filum (“fatty filum” or “filum lipoma”)^{24,25} and/or a filum diameter greater than 2 mm (“thick filum”) (► Fig. 25.1). Although such findings (low conus, fatty filum, and thick filum) may be seen occasionally in isolation in a normal patient, the combination of two or more factors, coupled with the patient’s clinical status and/or the presence of bony dysraphism, should significantly increase the likelihood of finding a symptomatic tethered spinal cord.²⁶

Split-Cord Malformation (Diastematomyelia)

SCMs can be divided into two main types, classically termed *diastematomyelia*¹⁰ and *diplomylelia*, and were previously thought to have different embryologic origins. In an effort to provide a classification scheme with more consistent and clinically relevant terminology, Pang,^{27,28} building on the theories of Bremer²⁹ and the classification used by James and Lassman,⁴ suggested the use of SCM type 1 and SCM type 2. Type 1 SCM consists of two hemicords separated by an osteocartilaginous median septum, each housed in a separate dural sheath (► Fig. 25.2a). Type 2 SCM consists of two hemicords contained within the same dural envelope and separated by a fibrous septum (► Fig. 25.2b). Both SCM types are thought to be caused by an abnormal, persistent neurenteric canal between the yolk sac and amnion. This fistula later splits the neural canal and notochord by forming an endomesenchymal tract. The persistence of parts of the tract, the entrapment of different structures within it, or both, explain the subsequent development of associated malformations. Endodermal remnants predispose to the formation of neurenteric cysts and intestinal duplication, the lack of skin closure dorsal to the tract causes a dermal sinus

tract that may form a dermoid cyst, and the entrapment of neural crest elements within the endomesenchymal tract allows the formation of paramedian nerve roots and meningocele manqué.²⁸ A persistent endomesenchymal tract interfering with normal neurulation of the adjacent neural tube may explain the known association of SCM with open myelomeningocele.

Most if not all patients have *tethering* median septa, the residual of the neurenteric canal, that are not always visible on preoperative imaging studies. All lumbar SCMs have a low-lying conus and may have additional tethering lesions.²⁷

Meningocele Manqué (Dorsal Bands)

Meningocele manqué (dorsal bands) is an occult spinal lesion that, as the term implies, is a meningocele that failed to develop (from the French *manqué*, “missed” or “failed”) (► Fig. 25.3). According to James and Lassman,⁴ who coined the term, an open

meningocele “protrudes on the surface of the back and does not contain neural elements. But often, there are nerves that are adherent to the neck of the meningocele.” It is thought that a meningocele manqué is a meningocele that formed in the embryo, then underwent spontaneous healing or scarring. It is often described as a dorsal band with or without adherent nerve roots or dorsal root ganglia. These bands start in the intrathecal structures and extend up into the dura or lamina, thus possibly tethering the spinal cord. Histologically, these bands are composed of fibrous tissue that often contains meningeal elements. Most of these lesions are associated with other intradural lesions.^{30–33}

Dermal Sinus and Associated Tumors of Disordered Embryogenesis

Dermal sinus ► Fig. 25.4) and tumors of disordered embryogenesis result from incomplete separation of the neural ectoderm

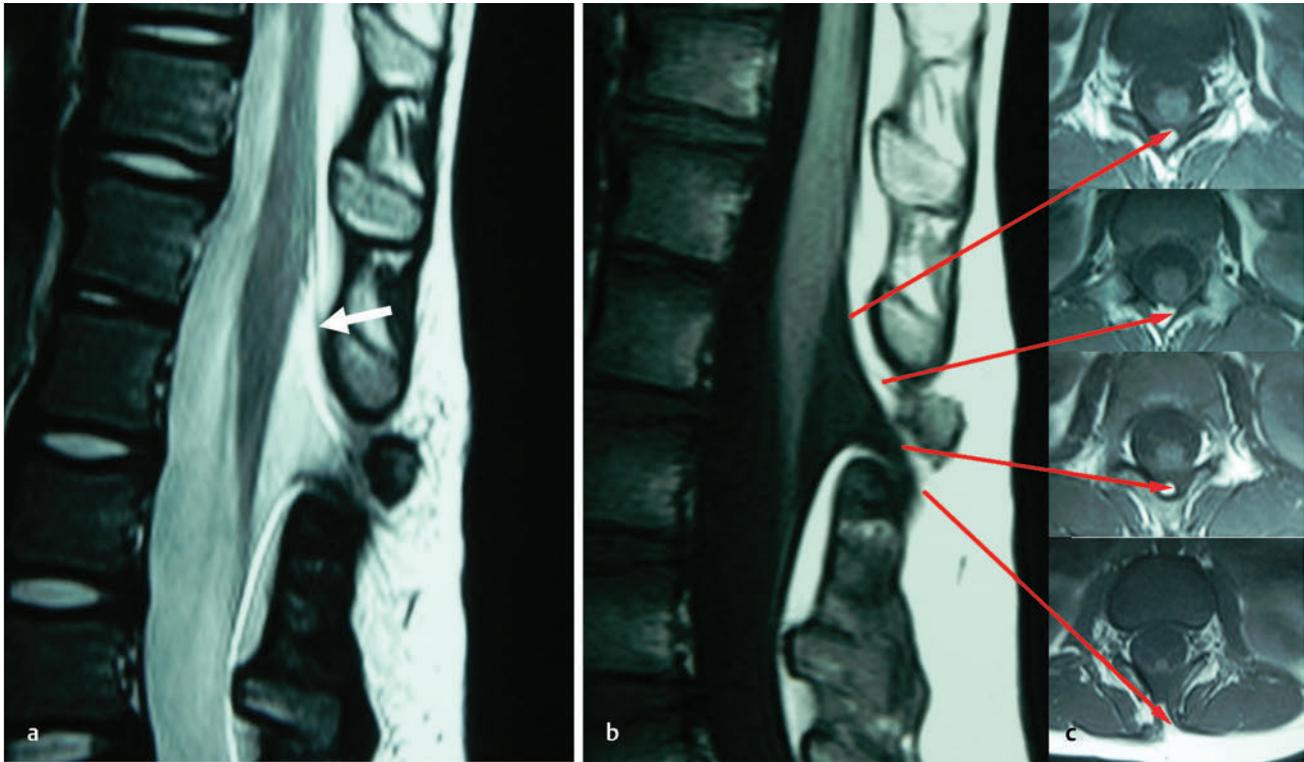

Fig. 25.3 (a) T2-weighted sagittal magnetic resonance (MR) image showing features of meningocele manqué, including a meningocele, tapered conus, dorsal tethering bands (*arrow*), and a rudimentary disk at level of the dysplastic lamina. (b) T1-weighted MR image of the same section as in (c) axial images. Adjacent axial images show a dorsal lipomatous stalk descending from the conus to exit the spinal canal through a bifid spinous process and passing into the subcutaneous fat (lowest image).

from the epithelial ectoderm (incomplete disjunction).³⁴ Dermal sinuses occur most commonly in the midline at the lumbosacral junction but are known to occur anywhere in the midline from the sacrum to the nasion and in rare situations may be off midline over either the spine or cranium. The sinus is lined with epithelium encased with dermis and fibroglial tissues. There may be hair protruding from the orifice of the sinus, itself often surrounded by avascular nevus. Most sinuses pass into the intradural space to end on the filum terminale or the conus. It is rare that they end in the subcutaneous tissues or extradural space.³⁵

Tumors may occur either independently or in association with a dermal sinus tract. Dermoid tumors occur in 80% of patients and contain elements from two germ layers (e.g., skin, hair, sweat, and sebaceous glands). Epidermoid tumors (20%) contain only desquamated cells from the epidermal layer. Intradural teratomas, which are more unusual, contain elements from all three germ layers. Malignancy is rare. Dermoid tumors may present as a midline subcutaneous mass, may be embedded in the central canal of the spinal cord, or may appear anywhere between these two extremes. The wall of the cyst contains the epithelial elements that are associated with regrowth of the cyst; thus, the focus of the resection must be to remove all epithelial remnants if possible.^{4,34}

Terminal Syrinx

A terminal syrinx (► Fig. 25.5^{30,36}) is a cystic dilatation of the lower third of the spinal cord. It generally occurs cephalad to

other OSD defects (tight filum terminale associated with an anorectal anomaly, meningocele manqué, diastematomyelia, and lipoma of the conus) and less frequently with other spinal cord anomalies.³⁰ It is present in about one-third of cases of OSD evaluated by magnetic resonance (MR) imaging, and two-thirds of these are large and likely to cause pain, motor weakness, and bowel and bladder deficits. Terminal syrinx should be suspected as a cause of delayed deterioration in function in a patient with OSD.

A myelocystocele (► Fig. 25.6) is probably a severe form of terminal syrinx that balloons out to form a large terminal cyst that tethers the spinal cord. The cyst sits in a large cavity that consists of an arachnoid-lined meningocele.^{37–39} This meningocele is in continuity with the subarachnoid space and is associated with dorsal bony dysraphism. The myelocystocele may be continuous with a syrinx and may be associated with a lipomatous mass, hence the terms *lipomyelocystocele* and *cystolipomyelomeningocele*.⁴⁰ For unknown reasons, myelocystoceles have been strongly associated with the teratogenic agent retinoic acid, as well as with the OEIS (*omphalocele, cloacal extrophy, imperforate anus, spinal anomalies*) syndrome.^{41,42}

25.3 Pathophysiology

Intradural dysraphic lesions cause neurologic deficits in several interrelated ways: (1) They may be due to abnormal formation of the neural structures during intrauterine development; (2)

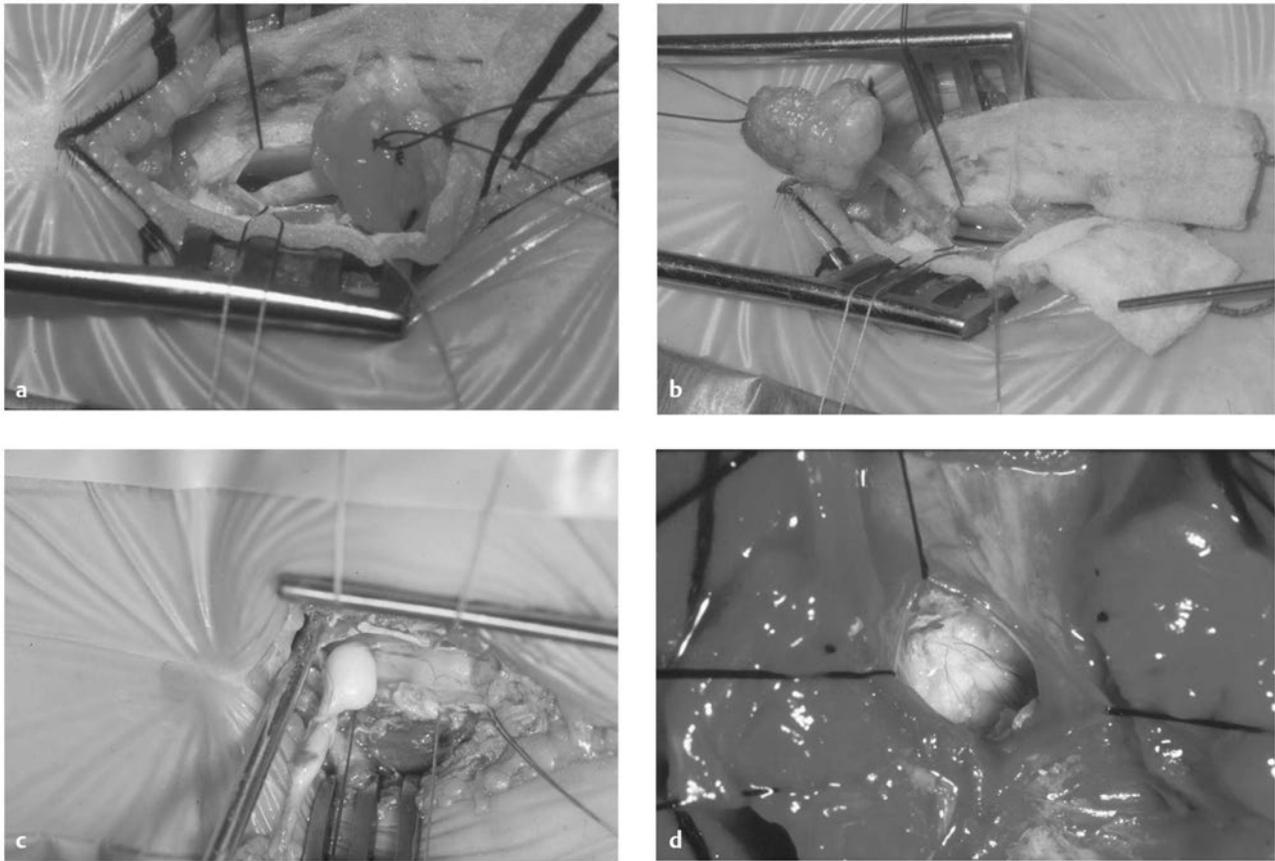

Fig. 25.4 (a) Dermal sinus and tract passing through dura to attach to the dorsal surface of the conus. (b) Dermal sinus tract is easily separated from the cauda equina and filum. (c) Dermoid tumor in the dermal sinus tract. (d) Dermoid tumor containing desquamated epithelium and hair.

lesions such as a lipoma of the conus or tumors of disordered embryogenesis may compress or expand within the conus medullaris; and (3) these lesions may cause traction on the radicular and medullary vasculature, spinal cord, and nerve roots by tethering these structures to surrounding spinal canal, dura, or extradural tissues. Such tethering is thought to interfere with normal, growth-related cord, root, and vascular motion, resulting in excessive tension within the cord.^{16,43,44} Tethering may cause traction on the conus medullaris or cord caudally (e.g., tight filum terminale and lipomyelomeningocele); dorsally (e.g., meningocele manqué, dorsal band, and dermal sinus tract); ventrally (e.g., ventral band, diastematomyelia, and neurenteric cyst); or in several directions simultaneously (varieties of complex lipoma of the conus). In addition, neurologic impairment may be due to meningitis or abscess complicating a dermal sinus or to hemorrhage into a neurenteric cyst.

Tethering is thought to be a major contributor to the deterioration in function noted over time in patients with OSD.^{16,45-47} Experimental evidence has shown that traction causes ischemic changes to the spinal cord.^{16,43-46} Repetitive flexion and extension of the spine and other sudden violent movements of the body are thought to cause ischemia to the tethered spinal cord as well as direct trauma at the point of fixation.^{16,48,49} Repetitive motion of the cord and roots, driven

by cerebral spinal fluid (CSF) pressure and flow changes, is also likely to be contributory to cord injury.⁵⁰ Similarly, spinal cord traction is thought to worsen with growth of the spinal column during childhood, thus explaining the progression of the neurologic deficit over time. Traction on the spinal cord is seen to cause maximal cord elongation in the lumbar region, with less physical damage or “stretchability” in the thoracic and cervical areas.^{16,48} This finding fits the usual clinical scenario of maximum lumbosacral cord dysfunction with the tethered cord syndrome. MR imaging of cord motion has confirmed that cord motion is decreased in patients with tethering and has suggested that the prognosis for neurologic recovery is worse in patients who had markedly decreased cord motion preoperatively.⁵¹⁻⁵³

25.4 Presentation

25.4.1 Signs and Symptoms

Patients with occult spinal dysraphism (OSD) may present with a combination of cutaneous, orthopedic, urologic, and neurologic signs and symptoms. The box “Signs and Symptoms of OSD” (p.312) lists the patterns of clinical presentation and manifestations that suggest the diagnosis of OSD.^{4,54} As the knowledge of OSD broadens among practitioners, many cases will be

recognized in infancy and childhood based on the clinical syndrome of cutaneous anomaly, subtle or progressive neurologic deficits including urinary incontinence, and musculoskeletal asymmetry.

Patterns of Clinical Presentation

- Asymptomatic infant with cutaneous marker
- Asymptomatic infant or child with caudal regression syndrome
- Symptomatic child with incontinence/evolving neurologic or orthopedic anomalies.
- Symptomatic child with secondary incontinence and a normal filum on MR imaging (occult tethered cord syndrome).

25.4.2 Clinical Context

The clinical context in which the patient presents can be the same for a number of pathologic forms of OSD. Although certain cutaneous markers and skeletal deformities are relatively specific for underlying spinal cord abnormalities (see box “Signs and Symptoms of OSD” (p.312)), many are not and are defined only after spinal MR imaging or ultrasound. In general, the clinical presentation falls into one of the following categories:

- Asymptomatic infant with cutaneous marker
- Asymptomatic infant or child with caudal regression syndrome

- Symptomatic child with incontinence/evolving neurologic or orthopedic anomalies
- Symptomatic child with secondary incontinence and a normal filum on MR imaging (occult tethered cord syndrome)

Signs and Symptoms of OSD

- Cutaneous stigmata
- Hypertrichosis
- Orthopedic deformities
- Foot and leg deformities and asymmetry
- Scoliosis
- Urologic problems
- Neurogenic bladder
- Urinary tract infections
- Incontinence
- Neurologic symptoms and signs

– Infants
Decreased spontaneous leg movement

Absent reflexes

Leg atrophy hidden by baby fat

Foot asymmetry

– Toddlers

Development delay (walking)

Abnormal gait

– Older children

Asymmetric motor and sensory dysfunction

Painless foot burns

Upper motor neuron signs (hyperreflexia)

Back and leg pain

– Young adults

Back and leg pain, either chronically or acutely after trauma or hyperflexion

Spasticity and hyperreflexia

– Any age

Meningitis

Paraplegia

Asymptomatic Infant with Cutaneous Marker

The incidence of significant cutaneous lesions of the craniospinal axis in the general population of neonates was found to be 3% in a large prospective study,⁵⁵ whereas in patients with OSD, the incidence approaches 80%,^{4,7} and it is common for two or more cutaneous lesions to coexist.⁵⁶ Cutaneous anomalies occur in the midline of the back, are above the level of the coccyx, and commonly overlie the spinal lesion. In general, the complexity of the cutaneous lesion reflects the degree of developmental anomaly of the underlying neural structures (see box “Signs and Symptoms of OSD” (p.312)). The cutaneous lesions associated with abnormalities of the filum, tethering bands, tracts, and neurenteric cysts include dimple, subcutaneous lipoma, dermal appendages, deviated or forked intergluteal cleft, vascular nevus, and/or pigmented nevus.⁵⁷

In *hypertrichosis*, tufts of hair may be sparse but more commonly are profuse, earning the name “faun’s tail” or “horse’s tail” (► Fig. 25.7a,b).^{2,4} There is a strong association between hair tufts and SCM, especially the form with a median bony septum (type 1). In the series of James and Lassman, hypertri-

chosis, especially the profuse form, occurred in 67% of cases of diastematomyelia with a median septum and in 33% of cases without a septum. In the same series, hypertrichosis also occurred in 24% of patients with spinal anomalies other than diastematomyelia.⁴

Atretic meningocele is a midline area that represents a meningocele that was present in fetal life and has subsequently atrophied or partially healed (► Fig. 25.7c,d). The skin can be quite thin, with the bluish hue of CSF underneath. Bands may connect the base of the skin defect to the dorsal surface of the spinal cord, and the lesion can be quite sensitive to touch, even in neonates. *Aplasia cutis* is often a small midline circular defect, in the past likened to a cigarette burn that commonly overlies a tethering dermal or fibrous tract. Atretic meningocele can be differentiated from aplasia cutis by the absence of the bluish hue in aplasia and the presence of a tract on imaging.

A *dermal sinus* is an opening in the skin that may connect to a subcutaneous tract lined by epithelium that can be traced to the dura or spinal cord (► Fig. 25.8). The orifice is commonly raised, with one or more stiff hairs sprouting, and it may have

at its base a cutaneous hemangioma or nevus. Intradurally, it may be associated with any of the other major dysraphic anomalies, and half of the tracts that enter the spinal canal end in a dermoid or other inclusion cyst or tumor.³⁴ A dermal sinus is especially significant among the cutaneous stigmata of OSD because in addition to its role as a sign of intradural pathology, it provides access for bacterial contamination that can result in local infection, meningitis, and/or intramedullary abscess.⁵⁸ Such infections do not always have cutaneous manifestations (i.e., redness, swelling around the sinus opening). A dermal sinus should be distinguished from the common sacrococcygeal or dermal pit. The latter is always located in the intergluteal fold directly over the tip of the coccyx. Coccygeal dermal pits are not associated with OSD, and when seen in isolation, they require neither surgery nor radiographic evaluation.⁵⁹

Dermal appendages can take many forms, some complex and reminiscent of abortive twinning^{60,61} (► Fig. 25.9). More commonly, they are simple, skin-covered mesenchyme-containing structures that resemble a tail. A *pseudotail* is any cylindrical outgrowth from the lumbosacral area (► Fig. 25.10); it is usually

Fig. 25.7 (a,b) Faun's tail. Luxuriant hair reminiscent of the tail of a satyr. (c) Infant with focal hirsutism superimposed on a background of flat capillary hemangioma. The central aspect of the lesion is composed of thin, atrophic skin and is exquisitely sensitive to touch. From the base of the lesion, strands of tissue extended to the dorsal surface of the spinal cord, which they tethered. (d) Aplasia cutis. The cigarette burn of old. This may mark a dermal tract without sinus, or meningocele manqué.

short and stumplike and may contain fat, cartilage, or other organ-specific tissue, such as embryonic kidney.^{62,63} In contrast, a *true human tail* is a remnant of an embryonic structure containing vertebrae, notochord, and spinal cord, as well as a sacral artery and vein; it may contain muscle in addition to adipose and connective tissues and may be curved, pigmented, or covered by hair; it is often “capable of spontaneous or reflex motion.”⁶²

An asymmetric or forked gluteal cleft is often associated with a capillary hemangioma or dermal appendage.

The presence of a capillary hemangioma, either flat or raised (strawberry), in the midline over the spine raises the suggestion of an underlying dysraphic defect,^{4,64} in particular when it is associated with other cutaneous anomalies (lipoma, dimple, asymmetric gluteal cleft). The incidence of underlying dysraphism is low with an isolated lumbosacral midline strawberry hemangioma⁶⁵ but is higher in the presence of a flat capillary hemangioma⁶⁶ (► Fig. 25.11). Like a capillary hemangioma, a pigmented nevus is rarely a marker of OSD when it occurs in

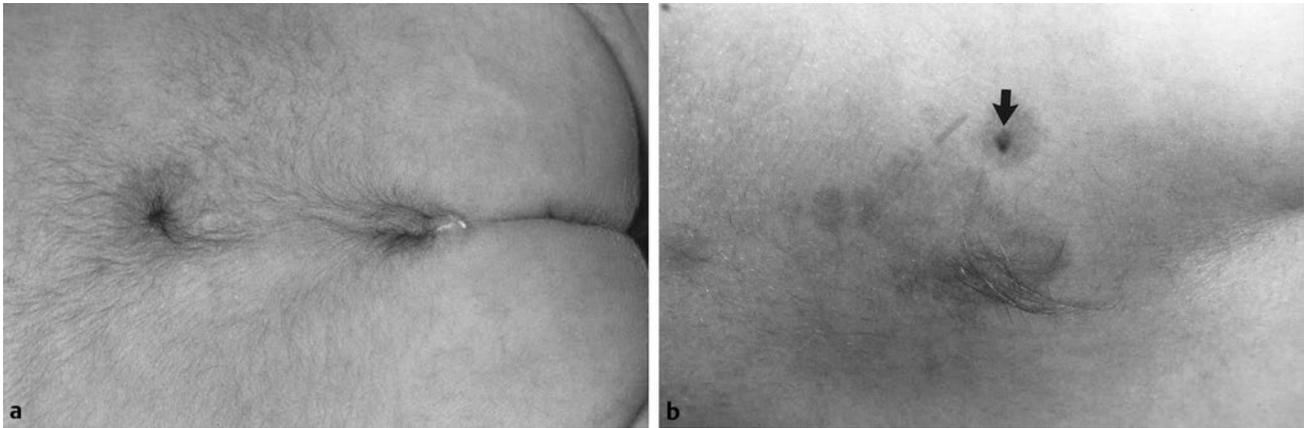

Fig. 25.8 (a) Dermal sinus—elevated orifice, stiff hair, and basal hemangioma. (b) Lumbar region of an infant with three cutaneous signatures of occult spinal dysraphism: dermal sinus (*arrow*), small area of focal hirsutism, and a flat capillary hemangioma under both of the other lesions. At operation, the dermal sinus was found to penetrate the dura and ascend to the conus; there was a short segment of diastematomyelia without a median septum, and the filum was enlarged and infiltrated with fat.

isolation, and mongolian spots are not markers of underlying spinal dysraphism.

These skin lesions are present at birth and often lead to an ultrasound or MR examination to detect intraspinal anomalies. The detection rate for tethered cord abnormalities varies in

individual series, some reporting a high sensitivity and others low.⁵⁷ Given the concerns regarding general anesthesia⁶⁷ in this age group, it is the practice of this author to defer general anesthesia for MR evaluation in an asymptomatic infant until after 1 year of age if the ultrasound assessment is nondiagnostic.

Asymptomatic Infant or Child with Caudal Regression Syndrome

Caudal agenesis⁶⁸⁻⁷¹ comprises a spectrum of sporadic congenital malformations arising from the caudal embryo. The range of hindgut and urogenital malformations^{69,70} that occur secondary to caudal agenesis include stenotic or imperforate anus; rectovaginal or rectourethral fistula; persistent cloaca resulting in a common urinary, genital, and intestinal outflow structure; and cloacal exstrophy. The complex developmental anomalies shown to be associated with spinal cord tethering include the following: (1) OEIS syndrome⁴¹ (omphalocele, cloacal exstrophy, imperforate anus, and spinal anomalies); (2) VATER syndrome⁷² (vertebral anomalies, anal imperforation, tracheoesophageal fistula, and renal radial anomalies); (3) VACTERL association (vertebral defects, anal atresia, cardiovascular anomalies, tracheoesophageal fistulas, renal anomalies, and limb defects, most often of the radius); and (4) the Currarino triad (anorectal malformation, sacral anomalies, and presacral masses). The more complex the developmental anomaly, the more frequently OSD is found,⁷³⁻⁷⁷ with incidence rates ranging from 15% in patients with an isolated imperforate anus (high or low)⁷⁸ to 60% in those with the VACTERL association.⁷⁹ Filum lipoma, thickened filum, lipomyelomeningocele, ependymal cysts, and myelomeningocele have been reported as the common tethering pathologies in these entities.

The role of the tethered cord in the functional impairment that these patients exhibit is not usually clear because of the pelvic floor, sphincter, and muscular malformations that directly affect urinary and bowel continence. Cord untethering is indicated for patients showing neurologic or motor deterioration; however, prophylactic untethering in the hope of improving continence is not necessarily indicated.⁸⁰

Infants with caudal regression syndrome have typical clinical findings.⁷⁰ A narrow pelvis results from the absence of vertebral segments and is accompanied by flattening of the buttocks, shortening of the intergluteal cleft, and prominence of the iliac crests. The missing coccyx and sacral elements may be obvious on palpation of the spine. Disturbance of lower extremity motor function is often accompanied by the relative preservation of sensory function. Treatment of the gastrointestinal and urogenital anomalies takes priority because of the possibility of life-threatening complications if they are left untreated.²⁵

Symptomatic Child with Incontinence/ Evolving Neurologic or Orthopedic Anomalies

No characteristic neurologic symptoms or signs occur in a patient with closed spinal dysraphism. The presentations range from back or leg pain, to subtle bladder disturbances detected with urodynamics, to a mild sensory disturbance in one foot, to severe motor deficits and resultant leg atrophy and deformity. The neurologic deficits are typically asymmetric, regardless of the type or location of the spinal lesion.^{4,9} Before a child begins to walk, it is often difficult to detect muscular weakness. Often, the deficit is mild and evidenced only by a slight asymmetry of the feet (possibly indicating long-standing motor weakness) or a predisposition to painless foot ulcers. The difficulty with diagnosis is especially true in newborns, in whom a thorough neurologic examination is particularly challenging and in whom

lower extremity changes become more evident over time as a consequence of the effects of muscle imbalance, weight bearing, and gravity on developmentally malformed bone and joint structures.⁸¹ Even unilateral atrophy of the leg muscles in an infant may be hidden by the abundant subcutaneous fat, and decreased spontaneous movements or an unusual posture of one extremity or asymmetric use may be an indication of subtle motor weakness.⁴⁵ Delayed or asymmetric ambulation in an infant may be the initial complaint.

Rarely, infants with terminal myelocystocele may deteriorate quickly. The deterioration may be due to an increase in CSF volume within a terminal myelocystocele and syrinx⁸² and/or displacement of CSF into a terminal syrinx, with cord distention caused by supine positioning. Acute deterioration can also occur as a result of hyperflexion movement(s).

Unilateral or bilateral foot deformities⁴ are the most common deformities reflecting OSD and include club feet; valgus, varus, and cavovarus deformities; hallux varus; asymmetric toe size; and trophic foot ulceration. Anomalies may be subtle, especially in infancy, and may consist of an increase in the web space or a difference in the slope of the arch; these are best viewed by looking at the soles of both feet simultaneously. Buttock asymmetry with a lateral curve to the upper part of the gluteal crease is a subtle sign that can easily be overlooked. Spasticity, as well as analgesia-related trophic ulcers and fatigue fractures, may also be obvious in an older child.^{4,83,84} Because of underlying malformed bone and joints, a foot deformity may worsen after repair of a spinal anomaly.^{4,81}

Patients harboring a dermal sinus usually present because the cutaneous marker is recognized. However, if this is missed or its significance is not appreciated, meningitis, often due to *Staphylococcus aureus*, *Escherichia coli*, or *Proteus* species, is the most common mode of presentation.¹³ Infection of an associated intraspinal dermoid tumor can result in acute paraplegia from either conus or cauda equina compression. As with other intradural tumors, spinal pain is a prominent feature.

Depending upon age, scoliosis occurs in up to 25% of patients with a tight filum terminale and 90% of patients with SCM. Factors that increase the likelihood of an intraspinal anomaly included the following: (1) thoracic curve convex to the left (23% of patients with left thoracic scoliosis had an intraspinal anomaly, versus 8% of patients with other curve patterns); (2) age younger than 11 years; (3) severe scoliotic curvature (the major curve averaged 57 degrees for the group with intraspinal anomalies and 28 degrees for the others); and (4) rapid progression of the curve (average of 28 degrees per year).⁸⁵

Symptomatic Child with Secondary Incontinence and a Normal Filum on Magnetic Resonance Imaging (Occult Tethered Cord Syndrome)

Children who present with incontinence but no structural or functional urologic abnormality should be investigated for evidence of OSD, whether or not they have a cutaneous marker. The loss of urinary control may be primary when daytime and nighttime continence has never been acquired, or secondary when loss of control occurs after a period of normal daytime and nighttime continence. Several series have reported

improvement in incontinence following section of a structurally normal filum associated with a normally positioned conus.⁸⁶⁻⁸⁹ At the present time, the clinical and urodynamic characteristics that predict continence following filum section are not clearly defined, and opinion among experts differs as to the role of untethering.⁹⁰ It is hoped that a randomized clinical trial, currently in process, will provide clarity as to the operative indications in this clinical context. Until the results of this study are available, section of the normal filum for incontinence should be considered experimental.

25.5 Diagnostic Studies

25.5.1 Magnetic Resonance Imaging

Spinal MR imaging is the imaging procedure of choice to diagnose and follow patients with OSD. Its multiplanar imaging capability and the ability to visualize and differentiate neural tissue make it an ideal tool for congenital disorders of the spine. Complete imaging of the spinal cord is required to ensure the recognition of multiple “skip” lesions and the hindbrain herniation seen rarely in patients with lipomyelomeningocele and myelocystocele.⁹¹

T1-weighted images provide clear anatomical detail of the spinal cord and filum terminale, allowing visualization of the vertebral level of the conus; the presence or absence of fat within the cord, spinal canal, or filum; and the size of the filum. T2-weighted images allow the identification of spinal cord tumors such as dermoids and epidermoids. In addition, they highlight intramedullary fluid-containing structures such as syringes, myeloceles,⁹² and neurenteric cysts.

The assessment of the filum terminale in patients suspected of having tethered cord syndrome has been difficult, particularly in the situation in which the filum appears normal and the conus terminates at a normal level. With the improvements in imaging resolution, the ability to recognize abnormalities in the structure of the filum has also improved. The majority of patients with a thickened filum have fat and fibrovascular tissue on histologic examination.⁹³⁻⁹⁵ Fat in the filum is always found at the junction of the filum with the caudal dural tube and involves more of the rostral filum in individual patients. If the filum immediately caudal to the conus is free of fat for 13 mm or more, it appears that symptomatic cord tethering is unlikely.⁹⁶

A variety of MR imaging sequences have been developed to evaluate cord motion, with the ultimate goal of being able to predict which lesions will require surgical untethering and to assess postoperatively the effectiveness of such procedures.^{51-53,97} Unfortunately, the goal of being able to use MR imaging to predict which patients will require untethering has not yet been achieved.

25.5.2 Ultrasonography

The role of ultrasonography in the evaluation or follow-up of patients with suspected closed spinal dysraphism is limited. Although it allows the operator to appreciate cord motion, its lack of spatial resolution limits its ability to define the causes of cord tethering. Despite these limitations and because of its low cost, ease of use, and minimal sedation requirements, ultrasonography has been used as a screening tool^{65,92,98,99} for

asymptomatic infants with sacral dimples or isolated strawberry hemangiomas in whom the findings of a normal conus location, “normal” filum, and normal filum, conus, and root motion would allow the clinician to postpone MR imaging. In each of these situations, the probability of cord tethering/OSD is known or presumed to be low.^{26,95} However, when a diagnosis of OSD is suggested by clinical or other radiographic findings, or when the study is inadequate for technical reasons, spinal MR imaging is required, in particular to show subtle anatomical lesions. Ultrasonography has a specific role to play in the assessment of myelocystocele in infancy. The meningocele and myelocele fluid spaces are easily resolved, and the continuity of the myelocele with the central canal can be confirmed by gentle ballottement of the postsacral mass. This finding can be used to differentiate myelocystocele from lipoma of the conus.

25.5.3 Urodynamics

The objective monitoring of bladder function is often fraught with difficulty of interpretation, especially in infants and children, because cooperation with the study is an intricate component of the evaluation. The usefulness of urodynamic studies lies in the following: (1) the evaluation of patients who are being assessed for incontinence and whose imaging studies are normal,^{86,87,100} (2) the monitoring of neurologic function when a nonoperative approach has been elected for an infant or child with conus lipoma,⁵ and (3) the comparison of function before and after surgical untethering. A validated scoring system has been developed that describes urodynamic abnormalities in children.¹⁰¹

Significant derangements in filling capacity, pressure, compliance, and contractility are found in patients with OSD.¹⁰² Improvement has been demonstrated postoperatively.^{28,86,103} The use of urodynamic testing in the preoperative evaluation of patients and in the postoperative, long-term follow-up of selected patients is recommended.

25.6 Treatment

25.6.1 Natural History and Surgical Decision Making

Randomized studies comparing the natural history of OSD defects with clinical outcomes after operative intervention have been conducted infrequently.^{104,105} In part, this is due to the fact that historically, the disparate conditions grouped as OSD were viewed as having natural histories, surgical outcomes, and operative risks that were of similar magnitude regardless of the etiology. As a result, assumptions regarding the effects of cord tethering and the presumed long-term benefit of operation were generalized to a varied group of pathologic entities. Because the risk for operative neurologic injury is low in many entities, and because clinically apparent “neurologic deficit” is more common in older children, early operation, before the development of deficit, was recommended as a standard for all forms of OSD.

With the improvements in imaging and with further clinical experience, it has become apparent that the forms of OSD differ markedly in the ease and safety with which they can be surgically treated and in the effectiveness of surgery to address

present and future clinical symptomatology (see box “Signs and Symptoms of OSD”). Surgery can address mass effect and in most cases cord tethering, but it does not address congenital myelodysplasia or predictably reverse established clinical defects.^{5,9,106–108}

The underlying OSD state is of critical importance in determining (1) the evolution of symptoms and signs, including their clinical presentation; (2) the natural history, including that which is due to myelodysplasia, mass effect, and tethering; and (3) the safety and long-term efficacy of surgery. Both historical and contemporary surgical series demonstrate that patients' symptoms and signs are more likely to be recognized as they age.^{104,105,109,110} They also demonstrate that deficits (musculoskeletal, neurologic, and urologic) are more likely to improve or be reversed if appropriate treatment for the cause of deterioration is undertaken in a timely fashion following the onset of the deficits. Unfortunately, in many patients, it is not possible to determine whether a deficit is truly new and has a surgically treatable cause or whether it is due to congenital myelodysplasia that becomes evident as development progresses. The assumption that all children are normal and that deterioration is the result of surgically correctable lesions has led to the conclusion that patients with OSD, if untreated, will progressively lose neurologic function with time. This thesis also assumes that the risks of surgery are minimal and that the efficacy will be long-lived.

In general, simple OSD responds predictably to surgical intervention, whether for untethering (tract excision, excision of tethering bands, filum section) or tumor excision. As the operative procedures are in most situations straightforward, the intervention can be done with a low risk for neurologic injury.^{5,7,8,106,111–116} Unfortunately, this assumption is not true for patients with complex OSD and may not be true for those with simple forms that may retether symptomatically.^{117,118}

25.6.2 Results of Surgical Treatment

The probability that a patient will recover from neurologic, urologic, and musculoskeletal symptoms varies with the cause of the symptoms and their duration. In general, a patient with fixed deficits or complete neurogenic bladder dysfunction does not recover as a result of operation, whereas a patient with progressive, evolving defects of musculoskeletal or neurologic function does recover to some degree. In the complex forms of OSD, a single untethering is not necessarily curative, and recurrence of similar or different symptoms is to be expected over the lifetime of the patient.^{5,7,9,106}

Urologic dysfunction often improves after an OSD untethering operation.^{27,86,87,119–123}

Back and leg pain is almost always relieved postoperatively.^{5,15,27,30,123,124}

Scoliosis responds differentially in simple and complex OSD. In the former, scoliosis if minimal will resolve with untethering, but complex OSD, in particular SCM, may be associated with structural vertebral anomalies that lead to progression.

The intraoperative risk for neurologic impairment, most commonly to bladder function, is less than 10%, with acute risk to sensory and motor function less for initial untethering operations.

25.6.3 Preoperative Evaluation

Routine preoperative laboratory testing and MR imaging of the spine comprise the usual evaluation before surgery. Spinal computed tomography (CT) can be very helpful in determining the challenges to laminectomy and lateral resection to provide access. Urodynamic testing is useful in determining the preoperative urologic status.

25.6.4 Intraoperative Neurophysiologic Monitoring

The purpose of intraoperative electrophysiologic monitoring is to distinguish between functioning nerve roots and spinal cord tissue and nonfunctional tethering structures that can be sectioned, thus minimizing neural injury.¹²⁵ Three main electrophysiologic techniques have been used in the operating room: (1) tibial and peroneal somatosensory evoked potentials (SSEPs), which theoretically detect excessive traction or lateral pressure on the conus; (2) pudendal sensory evoked potentials, which detect injury to the S2–S4 segments (which are very vulnerable to injury during an untethering procedure and are below the stimulation territories of the standard lower

extremity SSEPs); and (3) free running electromyograms from lower extremity musculature including the anal sphincter and (4) uni- and bipolar stimulation of cord, roots, and/or tethering structures. Motor evoked potentials can be used to assess the effects of dissection on the cord.⁴⁵ Electrophysiologic improvement following surgical untethering can predate clinical recovery.¹²⁶

25.6.5 Surgical Technique

A *tight filum terminale* is approached through a laminectomy, laminotomy, or laminoplasty extending from S1 to the mid sacrum (► Fig. 25.12) or through the L5–S1 interlaminar space. Exposure of the distal 2 or 3 cm of the subarachnoid space is all that is needed to allow adequate exposure.¹²⁷ After the dural and arachnoidal opening, the filum is recognized by its posterior/midline location, the bluish discoloration, the absence of nodes of Ranvier, its vasculature, and the fat commonly seen infiltrating the structure. The filum is separated from surrounding roots, then rotated to ensure that there are no nerve roots adhering to the undersurface. The filum is then coagulated and divided, first proximally, then distally, if a specimen is to be sent for histologic evaluation. The cut ends of the filum infrequently retether,^{117,118,128} making the long-term outcome excellent.

The surgical management of SCM is based on the concept that the median septum is a tethering entity that should be removed. This is true whether the median septum is bony, fibrous, or cartilaginous (► Fig. 25.13). Before resection of the median septum and adhesions in a patient with type 1 SCM (diastematomyelia with septum) and kyphoscoliosis is undertaken, careful study of the spinal images, including three-dimensional CT scans, can be very helpful in that orientation of the hemicords relative to the surgical approach is fully appreciated. Great care must be taken while the laminae are removed because of the possible presence of transdural bands attached to the dorsal cord and the base of the bony septum. In type 1 SCMs, the septum is resected extradurally with rongeurs or a drill under magnification. The septum usually contains blood vessels that bleed briskly as bone is removed. The septum in SCMs usually occurs at the caudal end of the cord split, leaving the more rostral aspect of the split free of attachments. The free zone rostrally is a safe starting point for the resection.⁴⁵ Working in this safe zone, the surgeon resects the septum and the dural sleeve flush with the ventral surface of the canal. This opens the two dural tubes and permits a complete intradural exploration for tethering bands or dysplastic roots. Unless the two hemicords are widely separated, the ventral dural defect is not repaired. The dorsal dural defect created by the excision of the septum and its sleeve is repaired. The risk for neurologic injury

is highest during (1) the definition and removal of the deformed laminae and the spinous process(es) and (2) the removal of the dural sleeve. Preoperative surgeon orientation to the hemicords minimizes this risk. Symptomatic retethering is rare, although kyphoscoliosis may progress and require spinal fusion.

Split-cord anomalies without an osseous or cartilaginous median septum (type 2 SCMs) require exploration throughout the entire length of the split. The laminectomy and dural opening are less technically challenging. The fibrous septum is disconnected from the ventral dura by gently rotating the hemicords to one side, or by working between the two hemicords. Retethering is rare.

Meningocele manqué is tethered by dorsal band(s) that attach to the inner surface of the dura or pass through the dura to attach to the undersurface of the lamina. Occasionally, the dorsal bands are composed of nerve roots coming from the medial aspect of a split-cord anomaly. When these course dorsally and *not* ventrolaterally, they should be cut to allow total relaxation of the cord. If any question arises as to the functional nature of these elements, electrophysiologic stimulation may be useful. Long-term follow-up has shown that the majority of patients remain stable or improved. Associated lesions may be the reason for deterioration.³³

A *dermal sinus tract*¹²⁹ should be surgically explored and removed to its terminal insertion. Although occasionally it may seem to end at the dural surface on imaging studies, an intradural exploration is always warranted.³⁴ Insertion of the tract into an extraspinal *dermoid cyst* requires complete resection of the cyst. When the dermoid tumor is embedded within the conus medullaris, complete excision is technically difficult without incurring a neurologic deficit (► Fig. 25.4). In addition to their mass effect, dermoid cysts cause neural compression because of secondary infection within the dermal contents (intratumoral abscess). If an infection (meningitis or abscess) is present at the time of diagnosis and neurologic function is preserved, surgical exploration for excision may be delayed until the acute infection subsides.¹³⁰ In the face of progressive neurologic deterioration due to cauda equina and/or cord compression, intraspinal exploration is appropriate for abscess drainage and/or excision of the abscess or tumor.

25.6.6 Postoperative Care

Postoperatively, patients are nursed in a flat position to minimize orthostatic pressure of the CSF on the dural closure. This may not be possible for neurologically intact, active older infants, especially those undergoing untethering for simple OSD malformations. These children are allowed up in a parent's arms to settle. Patients are discharged on postoperative day 1 or 2. Foley catheters are inserted only in patients with a pre-existing neurogenic bladder, those undergoing untethering for complex OSD, or those harboring a tumor. It is removed postoperatively, and intermittent catheterization is started if the residual volumes exceed normal amounts. A short course of perioperative steroids may be administered to patients undergoing intramedullary surgical manipulation (complex OSD and dermoid cyst excision).

Tissue fluid or CSF leakage and seroma/pseudomeningocele are the most common nonneurologic complication of untethering.¹³¹ In the absence of infection, the fragility of the dura and

the need for dural grafts likely underlie these problems. Meticulous surgical technique in dural and wound closure usually suffices in most patients.

25.6.7 Retethering

The probability of retethering depends on the underlying OSD malformation, the surgical procedure undertaken, and whether postoperative meningitis or wound infection was present. Surgeons debate the role of graft material. The extent to which each of these parameters affects the retethering rate is unknown. Retethering after division of the filum terminale was thought to be rare; however, its occurrence is increasingly reported.^{117,118,128} The rate of retethering of more complex malformations is much higher and depends on the duration of follow-up.^{4-7,9,27,91,106,109,116,132,133}

Patients who experience late deterioration should undergo a repeated clinical and imaging evaluation to determine the cause. Possible causes include the development of a syrinx, retethering, and missed diagnoses or complications. Repeated untethering should not be limited to the lysis of adhesions. Other dysraphic lesions, previously undetected, should be sought and treated appropriately. Meticulous surgical technique plays a significant role in minimizing future arachnoiditis and retethering. Using a capacious dural graft tends to minimize the intradural crowding of tissues,¹³⁴ minimizing bleeding into the subarachnoid space tends to reduce the amount of arachnoiditis, and avoiding injury to or coagulation of the pial surface decreases the likelihood of the pia adhering to surrounding tissues. In general, the risks for further neurologic compromise and operative injury during repeated untethering operations exceed those risks at the time of the initial intervention.

25.6.8 Follow-up

Patients should be followed for the possibility of recurrent symptoms. They are usually evaluated in a neurosurgery or spina bifida clinic at 2 months following the procedure and yearly thereafter. Unless a syrinx is present, MR imaging is not repeated in asymptomatic patients. Patients with abnormal urodynamic studies preoperatively or those in whom abnormal bladder function develops postoperatively are evaluated with further urodynamic studies until the clinical and urodynamic measurements are shown to be normal. Scoliosis and genitourinary, neurologic, and bony abnormalities are addressed in the follow-up visits.

25.7 Conclusion

OSD comprises a constellation of spinal cord malformations that present with cutaneous, orthopedic, urologic, or neurologic dysfunction. These malformations cause traction on the spinal cord, which in turn causes ischemia as well as focal trauma to the cord and resultant neurologic deficits. The diagnosis is confirmed by MR imaging. The treatment of OSD should be based on a clear understanding of the underlying anomaly, its natural history, the etiologies for the patient's symptoms, and the risk and efficacy of surgical intervention. Operative intervention has been shown to halt the progression of symptoms in many patients, and to produce neurologic improvement in some.

Recurrence of symptoms and/or worsening disability is possible, and patients with OSD are best followed in a comprehensive, multidisciplinary clinic whose physicians have experience treating similarly affected children.

Pearls

- The cutaneous marker seen in an infant with OSD commonly predicts the underlying spinal cord abnormality.
- All newborns should be examined for dermal sinus in the immediate postnatal period. If a sinus is found, the high risk for meningitis requires that the patient be referred for imaging and excision of the sinus and any associated dermoid or epidermoid tumor before being discharged to home.
- The diagnosis of tethered cord syndrome should be considered in all patients with secondary incontinence regardless of whether the imaging findings are abnormal.
- All patients with caudal agenesis or hypogenesis should undergo imaging of the spinal cord to define any cord abnormalities.
- The imaging of patients with OSD must include all spinal levels and the craniocervical junction because multiple abnormalities are common and may be discontinuous. All lesions may require surgical treatment. When a lesion above the conus is explored (e.g., for an SCM), the MR images should be studied closely to assess the need for division of the filum terminale. If this is deemed necessary, the filum may need to be exposed through another incision or an extension of the same incision.
- Spinal cord ultrasound can be used in infants younger than 6 months of age to screen for many of the intraspinal abnormalities seen in OSD. MR imaging of the neural elements provides a definitive diagnosis, and CT will clarify the relationships of neural elements to osseous structures.
- Care must be taken in removing the lamina during OSD surgery. Dorsal bands originating from the dura or spinal cord may insert on the under surface of the lamina.
- To be considered pathologic (i.e., tethered), a conus at a normal level should be accompanied by objective findings of OSD, such as lamina defects, cutaneous signatures, or neurologic defects. Attention should be paid to the presence or absence of fat in the caudal filum.

26 Surgical Management of Complex Spinal Cord Lipomas

Dachling Pang

The partial resection of complex spinal cord lipomas is associated with a high rate of symptomatic recurrence due to re-ethering.¹ Since 1991, the author has performed more than 330 total or near-total resections of complex lipomas with radical reconstruction of the neural placodes, designed to minimize the preconditions of re-ethering. Twenty years of follow-up have proven the long-term benefits of this technique.^{1,2} I now strongly advocate for total resection of spinal cord lipomas and radical reconstruction of the neural placode over partial resection because aggressive surgery, contrary to traditional teaching, is safe and gives far better long-term progression-free survival.¹

The rationale for total lipoma resection is based on three hypotheses:

1. The high rate of symptomatic recurrence after partial resection is due to re-ethering.
2. Re-ethering is promoted by three factors: a tight content-container relationship between spinal cord and dural sac; a large, "sticky," raw surface of residual fat; and incomplete detachment of the terminal neural placode from residual lipoma.
3. Total resection can eliminate the factors conducive to re-ethering and thus reduces the probability of symptomatic recurrence.

The object of surgery is therefore to create conditions that will minimize re-ethering. The first condition relates to the fact that the normal spinal cord exhibits intradural motions to gravity and postural changes on ultrasonography and dynamic imaging.^{3,4} Reducing the content-container ratio and amplifying the degree of freedom of the cord within the dural sac must lessen re-sticking by limiting sustained contact between the cord and the dura, this sustained contact being intuitively a necessary condition preceding the formation of fibrous adhesions. To do this, the cord bulk must be drastically reduced. For large, rambling, "virgin" lipomas, this means resection of all or most of the fat down to the thin, supple neural placode. For redo lipomas, the hard, grasping cicatrix must also be removed. The aim is to render the thinnest, most pliant neural placode possible that can be atraumatically neurulated (sutured from pia to pia; see below) without distortion or strangulation to form a slender, round tube. (The term *neural placode* in lipoma is borrowed from the familiar essential element of an open neural tube defect [ONTD] to emphasise its equivalent "neural" nature once purified of fat. The synonymous use of the term in lipoma and ONTD is logical if one ponders the embryogenesis of the two entities (see below); the "placode" in each case represents the original embryonic neural plate blighted in its final completing process, one invaded by paraxial mesenchyme, the other thwarted in its midline dorsal fusion.) The raw, sticky lipoma bed is simultaneously concealed within the tube, and the sac is enlarged by a capacious dural graft. Finally, total resection also enhances the chances of terminal untethering.

26.1 Anatomy and Classification

In the literature, the nomenclature of spinal cord lipoma is imprecise and inconsistent. Here, we define the types of lipomas as follows:

26.1.1 Dorsal Lipoma

The lipoma-cord interface is entirely on the dorsal surface of the lumbar spinal cord, always sparing the distal conus (► Fig. 26.1). The junctional demarcation between the lipoma, cord, and pia, the *fusion line* (see below), can always be traced neatly along a roughly oval track, separating fat from the dorsal root entry zone (DREZ) and dorsal nerve roots laterally (► Fig. 26.2). The lipoma therefore never contains nerve roots. The lipomatous stalk runs through an equally discrete dorsal dural defect to blend with extradural fat. The uninvolved conus often ends in a thickened filum terminale.

26.1.2 Transitional Lipoma

The rostral portion of this type is identical to that of a dorsal lipoma, with a discrete fusion line and easily identifiable DREZ and dorsal roots. Unlike the dorsal type, however, which always spares the conus, the transitional lipoma then plunges caudally to involve the conus as the plane of the fusion line cuts ventrally and obliquely toward the tip of the conus, likened to making a slanting, beveled cut on a stick (► Fig. 26.3a). The lipoma-cord interface thus created may be undulating and tilted so that the neural placode is rotated to one side or even spun into a parasagittal edge-on orientation, but the neural tissue is always ventral to this interface (i.e., on the side of the nerve roots exit), and the DREZ and the nerve roots are predictably localizable lateral and ventral to the fusion line and therefore do not course through the fat (► Fig. 26.3b). There may or may not be a discrete filum. The dorsal dural defect extends to the caudal end of the thecal sac and may be much larger on the biased side.

26.1.3 Terminal Lipoma

Unlike the dorsal and transitional types, terminal lipomas insert into the caudal extremity of the conus without blending with the spinal cord or its root entry zones. All the sacral roots clearly leave the conus rostral to the lipoma, and in most cases the conus itself looks normal. The dural sac and the dorsal myofascial coverings are intact. The lipoma either replaces the filum entirely or is separated from the conus tip by a short, thickened filum.

The surgery for terminal lipoma is relatively straight forward and therefore beyond the scope of this chapter.

26.1.4 Chaotic Lipoma

This novel type is so named because it does not "follow the rules" of either the dorsal, transitional, or terminal lipoma. It

(b) Intraoperative picture shows neat oval fusion line around lipoma–cord interface in a horizontal plane. Note intact conus and caudal sacral roots.

begins dorsally in an orderly fashion, like a dorsal or transitional lipoma, but its caudal portion is *ventral* to the neural placode and does engulf neural tissue and nerve roots (► Fig. 26.4a). The fusion line may be distinct rostrally but quickly becomes blurred distally, and the location of the DREZ and nerve roots is less predictable. The moniker “chaotic” depicts the sometimes confusing blend of the ventral fat and neural placode, and the often impossible task of separating fat from neural tissue at surgery (► Fig. 26.4b). Chaotic lipomas are uncommon but are characteristically seen with sacral agenesis.²

The literature^{5,6} describes one other lipoma type, the lipomyelomeningocele, in which part of the distal conus extends into the extraspinal compartment, dragging with it a small collar of dural sac (► Fig. 26.5). The basic structure is that of either a transitional or a dorsal lipoma. Accordingly, we choose to classify this type as either a transitional or dorsal lipoma, with a descriptive qualifier of “extraspinal extension.”

26.2 Surgically Relevant Embryology

An understanding of the embryogenesis of lipomas is helpful in appreciating the surgical nuances.

26.2.1 Embryogenesis of Dorsal and Transitional Lipomas

In the embryo, a progressive disparity exists between the spinal cord and vertebral column as a result of the faster growth rate of the latter.^{7–10} The caudal end of the cord ascends gradually from opposite the coccyx in the 30-mm human embryo to the L1–L2 level at birth.^{9–12} Proper ascent of the cord requires a well-formed neural tube and a smooth pia–arachnoid covering. If during early development a dorsal defect exists in the dura

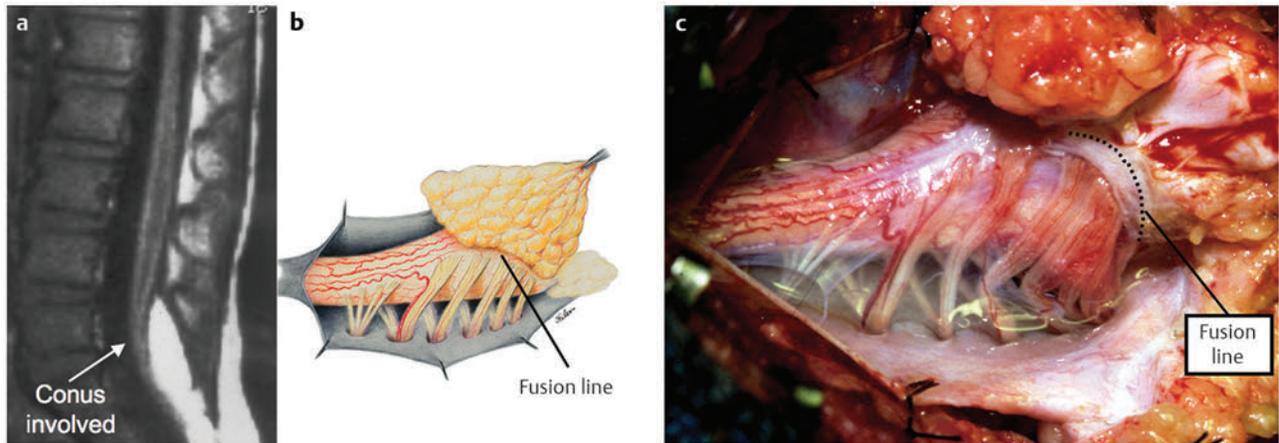

Fig. 26.3 Transitional lipoma. (a) Sagittal magnetic resonance image shows that lipoma begins dorsally but involves the entire conus. The ventral side of the neural placode is free of fat. (b) The plane of the fusion line begins dorsally, then cuts obliquely toward the tip of the conus. The array of DREZ and dorsal roots is also forced to slant dorsoventrally. (c) Intraoperative picture showing a massive lipoma but a very distinct dorsoventral fusion line separating fat from the DREZ and dorsal roots, which always lie lateral and ventral to the fusion line. The ventral side of the placode is always free of fat in a regular transitional lipoma

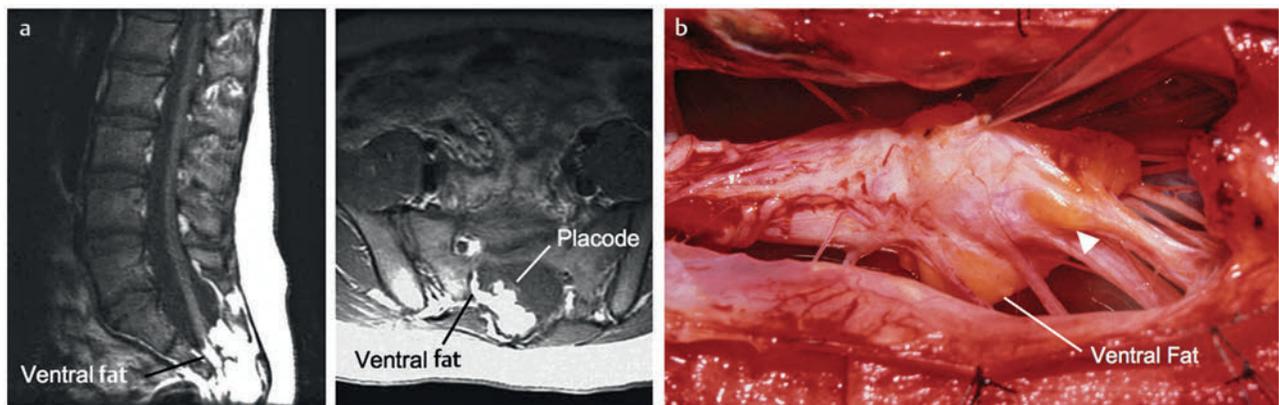

Fig. 26.4 Chaotic lipoma. (a) Sagittal magnetic resonance image shows ventral as well as dorsal fat in relation to the neural placode. Note sacral agenesis, with only two visible sacral segments. Axial image shows ventral fat and an extremely irregular lipoma-fat interface. (b) Intraoperative picture showing fat ventral to the placode and on one of the sacral roots (arrowhead). Note absence of a discrete fusion line.

(duraschisis) and neural tube (myeloschisis), mesodermal elements from the surrounding mesenchyme will enter the dural sac and form an attachment with the sliding neural tube in the form of a fibrofatty stalk, resulting in its entrapment. This theory features a fundamental defect in neural tube closure during primary neurulation (secondary neurulation does not involve dorsal neural fold closure), and thus it applies only to dorsal and transitional lipomas (see below). It is compatible with the observation that these two types of lipomas are always associated with neural arch defects.

Normal separation of the cutaneous ectoderm and neuroectoderm (disjunction) occurs *after* dorsal neural folds fusion, so that the surrounding mesenchyme is permanently segregated from the dorsal (ependymal) surface of the neural plate. The embryologic error leading to the mesodermal invasion of the neural tube probably lies in *premature disjunction* between the cutaneous and neural ectoderm^{13,14}, i.e., the separation of one from the other occurs *before* the converging neural folds fuse

with each other. This allows the paraxial mesenchyme to roll over the still gaping neural folds and enter the central canal. Once contact between the mesenchyme and ependymal neuroectoderm is made, further closure of the neural tube is permanently prevented, and a segmental dorsal myeloschisis is created (► Fig. 26.6a,b). Alternatively, the fault may lie in a delay in neural folds fusion secondary to an insufficiency of the paraxial mesoderm in impelling their dorsal convergence,¹⁵⁻²¹ so that ectodermal disjunction again precedes neural folds fusion. Lastly, faulty fusion of the neural folds due to a metabolic disturbance of the cell membrane-bound glycosaminoglycans, which are vital to cell-cell recognition and adhesion,²²⁻²⁵ can likewise reverse the temporal relationship between disjunction and neural folds fusion.

Experimental studies show that the pluripotential mesenchyme forms derivatives according to the inductive properties of the adjacent neuroectoderm (► Fig. 26.6c).^{26,27} The ependymal side of the neural tube induces mesenchyme to form fat,

muscles, collagen, and occasionally bone and cartilage, whereas the outer surface of the neural tube induces the formation of meninges.²⁸ However, no dura can now form over the dorsal opened portion of the neural tube, and the dural defect neatly surrounds the evolving lipomatous stalk, which tethers the neural tube to the subcutaneous adiposity. In like manner, deficiencies in the overlying myofascial layers (from myotomal mesoderm) and neural arches (from scleromesoderm) also neatly surround the lipomatous stalk (► Fig. 26.6d).

Within the neural tube, the intramedullary fat and muscles fuse with the developing alar and basal plates. Because the dorsal root ganglions develop from neural crest cells at the outer aspect of the neural fold lateral to the site of failed fusion, the dorsal nerve roots grow outward ventrolateral to, *but never traverse*, the lipomatous stalk. The DREZ must correspondingly lie very near, *but always lateral to*, the exact junctional boundary between the lipoma and spinal cord. This boundary, called the *fusion line*, is of tremendous surgical significance^{2,29,30} (► Fig. 26.6d). Meanwhile, the cutaneous ectoderm, long

detached from the neuroectoderm, heals over in the dorsal midline to form healthy skin over the subcutaneous lipoma.

The genesis of dorsal lipoma perfectly exemplifies mistimed disjunction during *primary* neurulation. Its fibrofatty stalk always involves cord segments above the conus, which forms mainly from secondary neurulation. Furthermore, the failure of primary neural tube closure appears to be *segmental*, and normal closure takes place—business as usual—immediately following the abnormal event. This “square pulse” nature is illustrated by the fact that the sharp fusion line between fat, spinal cord, and pia-arachnoid can be neatly traced circumferentially around the lipomatous stalk^{29–31} (► Fig. 26.2). Dorsal lipomas therefore result from a segmental closure abnormality *involving only primary neurulation*. They accounted for fewer than 15% of spinal cord lipomas in our series.^{1,2}

In transitional lipoma, the myeloschisis involves much more than an isolated segment of the primary neural tube. Even though its rostral part resembles the dorsal lipoma, the involvement of the whole of the caudal spinal cord means that not only primary but also secondary neurulation has been profoundly disturbed by the mesodermal invasion. This is supported by the observations that in many transitional lipomas, the filum is incorporated into the distal fat, and within the lipomas are often spaces resembling the vacuoles found within the secondary neural tube during its cavitory phase. Also, whereas the rostral part of the transitional lipoma is always dorsal and aptly reflects premature disjunction of primary neurulation, the distal part involves the core of the conus, a situation compatible with misguided mesenchymal inclusion during the much less orderly events of secondary neurulation. Intramedullary mesenchyme may migrate within the neural tube after invasion and travel caudally across the boundary from the primary to the secondary neural canal since the two neural canals are in continuity.³² In fact, the hypothesis that the rostral part of the transitional lipoma arises from aberrant primary neurulation (involving only the dorsal cord) and the caudal part arises from abnormal condensation of the secondary neural cord (affecting the deeper central core of the conus) furnishes at least one explanation for the

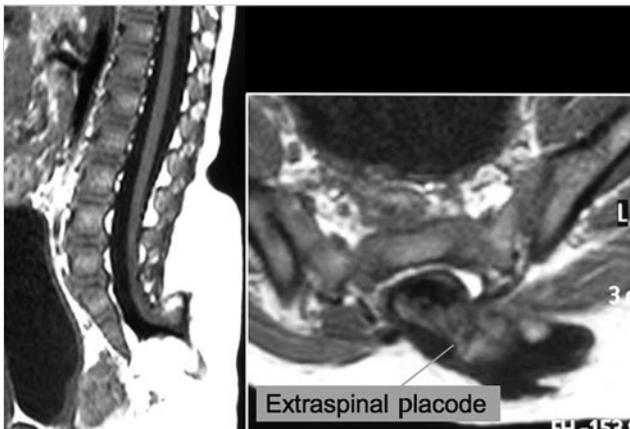

Fig. 26.5 Transitional lipoma with extraspinal extension (“lipomyelomeningocele”). The lipoma, cerebrospinal fluid sac, and part of the neural placode extend out of the spinal canal through a dorsal defect.

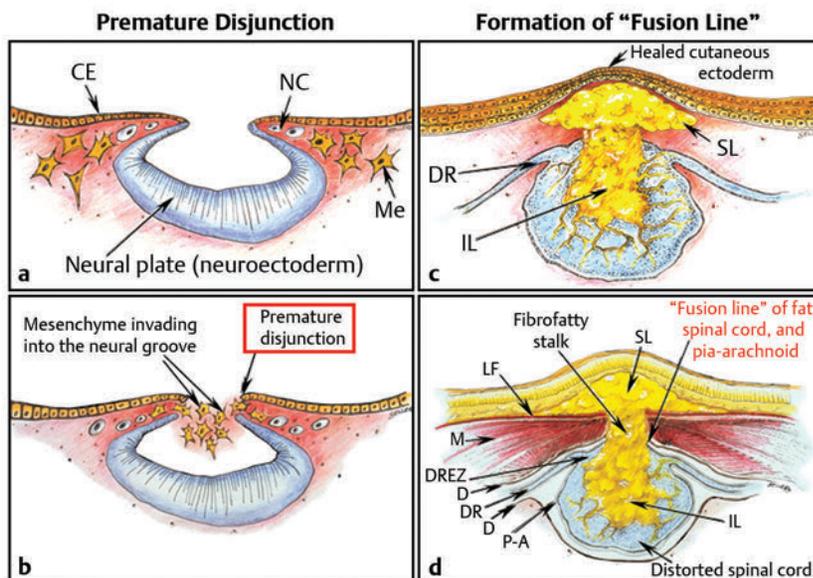

Fig. 26.6 Embryogenesis of a dorsal lipoma, a purely primary neurulation defect. (a,b) Premature disjunction before complete closure of the neural plates allows the migration of mesenchymal cells into the neural groove to be in contact with the ependymal surface. dorsoventral obliqueness of the lipoma–cord interface. Despite the larger field of involvement of the neural tube, the lipoma–cord interface remains relatively distinct in a transitional lipoma.

26.2.2 Embryogenesis of Chaotic Lipomas

Chaotic lipomas do not quite fit into either the dorsal or the transitional schema. They often do not have a distinct dorsal part with the symmetry of a dorsal lipoma, and the lipoma–cord interface is irregular and ill defined, with fat running through the neural placode to the ventral side in large and unruly measures. Even in the context of the less orderly transitional lipoma, the interplay between lipoma and cord in this type of lesion seems to be in constant chaos.

This degree of anatomical unpredictability in chaotic lipoma and its strong association with caudal agenesis (82% in our series²) suggest that the embryogenetic error occurs during the early stage of secondary neurulation as part of the general failure of the caudal cell mass (► Fig. 26.7).^{33,34} Secondary neurulation comprises three distinct stages: (1) condensation of neural material from the caudal cell mass to form the solid medullary cord; (2) intrachordal cavitation of the medullary cord^{32,34,35} and its integration with the primary neural tube; and (3) partial degeneration of the cavitory medullary cord through massive apoptosis to result in the thin filum terminale.^{9,32} It is possible that formation of the chaotic lipoma involves the entanglement of lipogenic mesenchymal stem cells with cells from the caudal cell mass during aberrant condensation of the medullary cord, forming an inseparable mixture of neural tissue and fat, with nerve roots projecting out haphazardly.²

26.2.3 Embryogenesis of Terminal Lipomas

Terminal lipomas result from abnormal *secondary* rather than primary neurulation, as evidenced by the unexcepted rule that the lumbar and upper sacral cord segments, products of

primary neurulation, are never affected in a terminal lipoma. Furthermore, dorsal myeloschisis and duraschisis, both hallmarks of failed (primary) neural fold fusion, are never seen. Lastly, the terminal lipoma either replaces or forms part of a thickened filum, which temporally places the pathogenetic process at secondary neurulation. The fact that the distal conus in terminal lipomas always remains fat-free argues against an abnormal condensation phase during early secondary neurulation. On the other hand, the terminal lipoma often contains (disorganized) spinal cord elements and ependymal tubules,^{36,37} which suggests rather an incomplete or ineffective degeneration phase at late secondary neurulation, possibly due to failed apoptosis.³⁸

26.3 Intraoperative Electrophysiologic Monitoring

Intraoperative monitoring has become a sine qua non in lipoma surgery.^{2,39,40} Elaborate electromyographic preparations are made to capture triggered motor responses from the relevant lumbosacral nerve roots. Standard electromyographic needles are inserted into the rectus femoris (L4), anterior tibialis (L4–L5), gastrocnemius (S1), and abductor hallucis (S2). Smaller-gauge (No. 27) electromyographic needles are inserted obliquely into the external anal sphincter through the anal verge on each side, which are insulated from each other by a plug of dry muslin gauze so that sphincter contractions from one side can be unequivocally distinguished from the other side.³⁹ All stimulations and recordings in our cases are done with the Cadwell Cascade Intraoperative Monitoring System (Cadwell Laboratories, Kennewick, WA) and the Cascade software version 2.0.

Stimulating needle electrodes are placed subcutaneously along the shaft of the penis in male patients and between the periclitoral skin and the labia minora in female patients. Stimulation of the sensory domain of the pudendal nerve via these electrodes generates an “electric” bulbocavernosus reflex, which is a form of H-reflex for the conus useful in monitoring the integrity of the central connections of the conus apart from motor root mapping.^{39,41}

Standard stimulating electrodes are placed near the posterior tibial nerve behind the medial malleolus and near the common peroneal nerve at the fibular neck to enable somatosensory evoked potential monitoring for the spinal cord segments above S2.³⁹

All motor root and direct spinal cord stimulations are done with a concentric coaxial bipolar microprobe electrode that has an end plate diameter of 2 mm (► Fig. 26.8). The concentric configuration and small size of the anode–cathode complex allow extremely focused current delivery to a very small target volume, thus making the electrode ideal for the fine discrimination of small and crowded electroresponsive units.² Stimulating currents from 0.5 to 3.0 milliamperes are used depending on target impedance. The stimulation frequency is usually set at 10 per second. This permits spontaneous random firing due to nerve irritation from surgical manipulation to be distinguished from rhythmic evoked contractions.

26.4 Surgical Technique for Total or Near-Total Resection

26.4.1 Step 1. Exposure

The skin and soft tissue incision should go straight through the subcutaneous lipoma if one is present. Removing this will leave behind a large subdermal space into which cerebrospinal fluid (CSF) can collect under tension and consequently hinder wound healing. Frequently, a discrete fatty stalk connects the subcutaneous with the intraspinal lipoma through a defect in the lumbodorsal fascia. This stalk is continuous with the spinal cord and cannot be tugged on during fascial dissection.

The upper extent of the bony exposure should include one level above the rostral end of the lipoma. This reveals, for proper orientation, the “last” normal set of nerve roots and DREZ before the lipoma resection is started. Wide laminectomy is essential to afford full access to the lateral edges of the dural sac (see below). Visualization of the normal dura rostral to any lipoma gives a depth perspective as to how far out the neural tissue

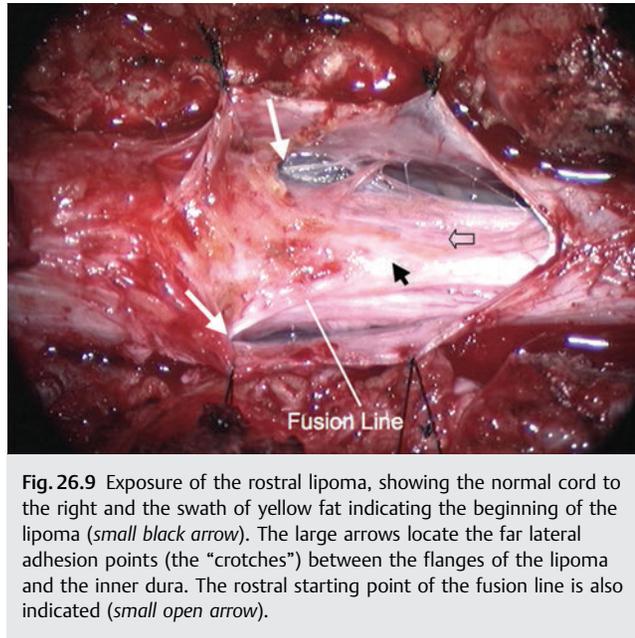

Fig. 26.9 Exposure of the rostral lipoma, showing the normal cord to the right and the swath of yellow fat indicating the beginning of the lipoma (*small black arrow*). The large arrows locate the far lateral adhesion points (the “crotches”) between the flanges of the lipoma and the inner dura. The rostral starting point of the fusion line is also indicated (*small open arrow*).

and CSF sac may have extruded beyond the plane of the dura. The heavy bulk of extradural fat can then be safely lopped off to give room for intradural dissection and lighten the tug on the conus.

26.4.2 Step 2. Detachment of Lipoma from Dura

The dura is always opened in the midline about 1 cm rostral to the lipoma regardless of whether it is dorsal or transitional. For a dorsal lipoma, the midline incision is then carried circumferentially around the discrete lipoma stalk and down the middle again to expose the conus (► Fig. 26.2a). For a transitional lipoma, the midline cut is carried right up to the lipoma, where the dura quickly thins out to nothing in the middle, although decent dura can usually be picked up just beyond the lateral edge of the lipoma stalk. Unlike with the dorsal type, the bifurcated dural incisions with a transitional lesion can seldom be made to rejoin neatly in the midline caudal to the lipoma stalk, usually not until the whole of the lipoma–placode complex had been exposed, many steps later (see below). At this stage, the freed-up portion of the dural edge on each side must be tautly and widely retracted with sutures. This is crucial maneuver because full lateral exposure of the intradural span, made possible by generous bone removal, reveals the “crotch” where the far lateral fringe of the lipoma attaches to the inner surface of the dura (► Fig. 26.9).

Next, the *fusion line* is identified, where the pia, spinal cord, and lipoma join in a continuous furrowed border that travels in a rostral to caudal direction, outlining the entire attachment of the lipoma stalk to the cord. In a dorsal lipoma, the fusion line forms a neat, *complete* oval or circle from side to side, usually upon a leveled horizontal plane, often bilaterally symmetrical, and always sparing the conus below (► Fig. 26.2a,b). In a transitional lipoma, the rostral fusion line starts distinctly enough but then edges ventrally toward the tip of the conus and tends

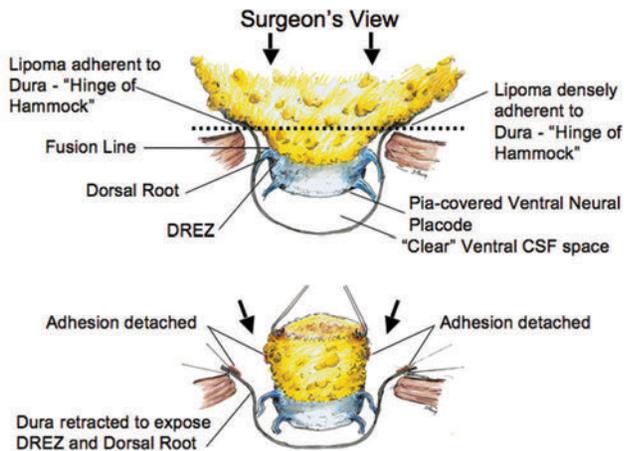

Fig. 26.10 Drawing depicting the relationships between the lipoma, neural placode, nerve roots, and dural sac in an axial slice. Upper: The lipoma-cord assembly is suspended at the dural edge at far lateral adhesion points, like a hammock against side hinges. The dotted transverse line that joins the two side hinges divides the assembly into a dorsal disorderly fibrofatty half that completely blocks the surgeon's view and a much more orderly ventral half containing the important anatomical landmarks of the fusion line, DREZ, dorsal roots, fat-free ventral placode, and pristine ventral cerebrospinal space. Lower: After the far lateral adhesion points (the hinges) have been detached by careful "crotch dissection" and the fatty mass has been folded in, the ventral anatomical landmarks can be visualized.

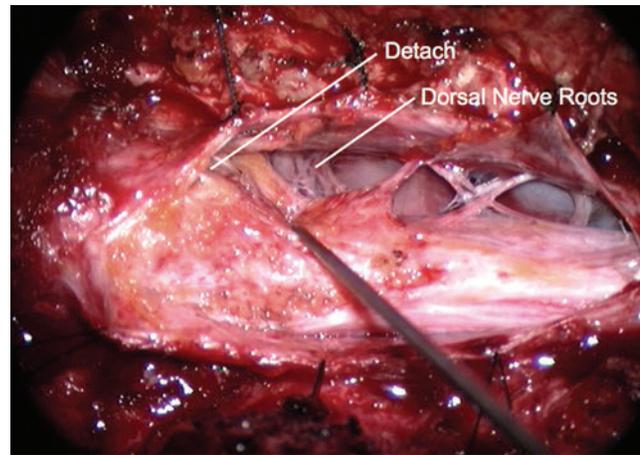

Fig. 26.11 Step 2 of surgical technique, "crotch dissection," in which the far lateral adhesion points between the fringes of the lipoma and the inner dura are sharply detached to unhinge the hammock of the lipoma-cord assembly. Note how the proximal sets of dorsal roots are revealed with just the first efforts to unhinge the hammock.

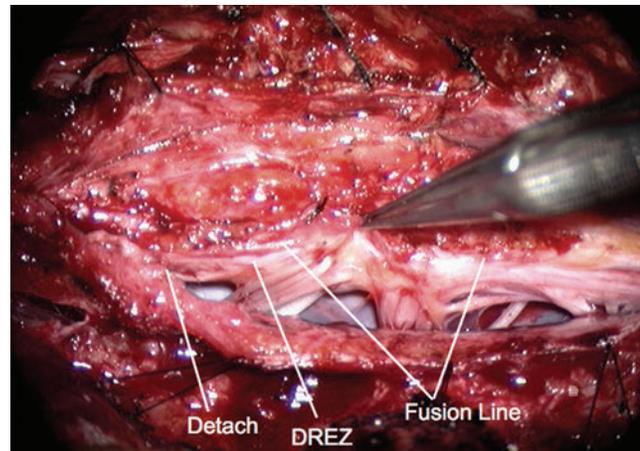

Fig. 26.13 Exposure of all relevant anatomy vital to the next stage of the actual resection of the lipoma: the fusion line, DREZ, dorsal roots, ventral side of the placode, and free cerebrospinal fluid space, in dorsal to ventral order. DREZ, dorsal root entry zone.

to wander laterally and asymmetrically, often becomes sheltered by the overhanging fat, and never meets its counterpart from the other side at the caudal end (► Fig. 26.3a,b).

True to the events of embryogenesis, the DREZ and dorsal roots are always lateral to the fusion line, and at the rostral end of the fatty stalk of both lipoma types, this orderly arrangement can be depended upon on both sides, thus presenting a convenient place at which to start the dissection. In most transitional lipomas, however, the more caudal nerve roots are quickly covered from view by the overflowing fat, which tends to fuse with the dura at a far lateral point (► Fig. 26.10 upper). Hence the

use of the term *crotch dissection*, which depicts the key step of grasping the overhanging fat and pulling it medially under tension against the tagged dural edge, then sharply separating the fat-dura attachment with the dissecting scissors (► Fig. 26.10 lower and ► Fig. 26.11). It is absolutely essential to lean the round curve of the scissors firmly against the inner lining of the dura while this attachment is cut to avoid blindly injuring the nerve roots, which project from the cord slightly medial to the "crotch" and lie just deep to the fat. The hidden roots should spring into view wherever the detached fat is pulled back, and they can be gently coaxed away from the dura by blunt dissection toward the exit foramina (► Fig. 26.12). At the same time, the free CSF space ventral to the dorsal roots and the fat-free, pia-covered ventral surface of the neural placode, hitherto hidden by the overhang, now "pop" into view (► Fig. 26.13).

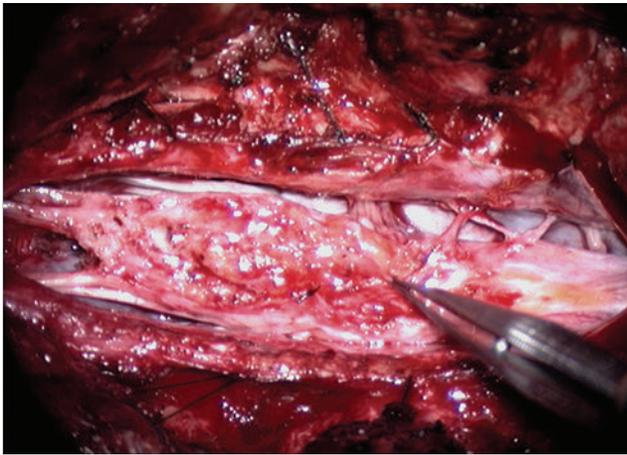

Fig. 26.14 Complete bilateral detachment of the adherent hinges and terminal untethering; the neural placode now “sinks” into the basin of the dural trough.

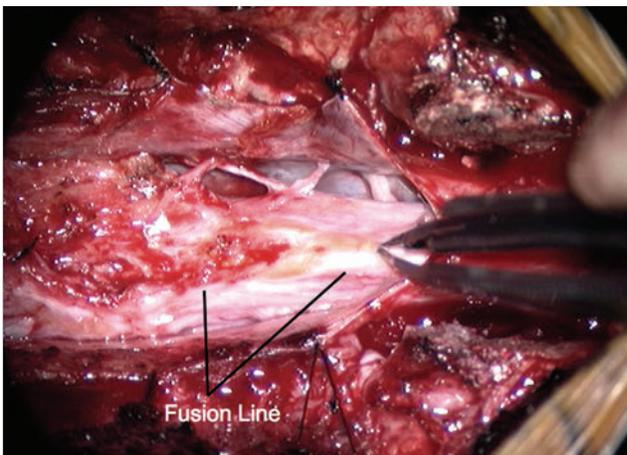

Fig. 26.16 Step 3 of surgical technique. Resection of the lipoma begins at the rostral end of the fat, at the semilunar edge showing just a small yellow swelling (at the points of the bipolar microforceps). Note the rostral fusion line and first pairs of dorsal roots.

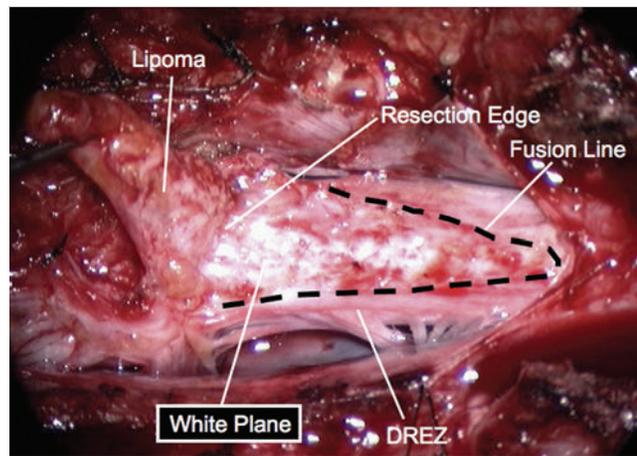

Fig. 26.17 The “white plane” of thin, glistening, fibrous netting separating fat from spinal cord, bounded always by the fusion line. Note the detached rostral portion of the lipoma lifted away from the white plane to show the resection edge. DREZ, dorsal root entry zone.

It is clear from this description that in each successive axial slice, all lipomas, big or small, dorsal or transitional, are roughly divided by a transverse line joining the points of the far lateral fat–dura attachment on each side, where the lipoma–cord assembly is in effect suspended like a hammock against two lateral hinges over an uncluttered ventral CSF pool. Dorsal to this transverse line is the visible but disorderly, massive, and unrevealing fat, and ventral to this line are the orderly fusion line, DREZ, dorsal nerve roots, neural placode, and ventral CSF space, but all initially made invisible to the surgeon by the overhanging fat (► Fig. 26.10 upper). The purpose of the “crotch dissection” is therefore to release this suspension so that the hammock of neural placode and nerve roots can be folded inward enough to be identified and preserved during the next phase of lipoma resection (► Fig. 26.10 lower).

This laborious but indispensable step of “crotch dissection” is carried all the way caudally (► Fig. 26.13) until all the “useful”

nerve roots are identified and the entire neural placode, with a profusion of lipoma still attached, is completely unsuspected from the dura and has literally “fallen” into the basin of the dural trough (► Fig. 26.14).

26.4.3 Step 3. Lipoma Resection

Resection of the lipoma begins at the rostral end, where the anatomical relationships between fat, DREZ, and nerve roots are clearly decipherable (► Fig. 26.15 and ► Fig. 26.16). Sharp dissection with microscissors is used to locate a thin but distinct silvery *white plane* between fat and cord at the demilune of the rostral fusion line (► Fig. 26.17). It takes some determination, for the initiate, to cut into this traditionally forbidden place, seemingly straight into the spinal cord right at the fusion line, but with experience, this white plane can be found in every case. We strongly discourage using the carbon dioxide

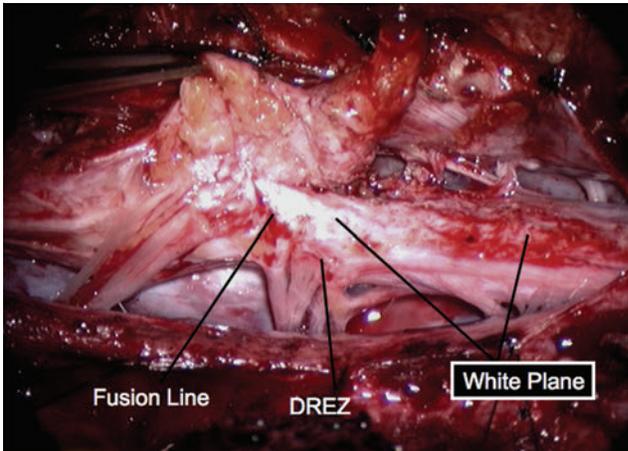

Fig. 26.18 At the outer margin of the white plane, dissection is kept strictly on the fusion line, thus reliably sparing the slightly more lateral DREZ and dorsal roots. DREZ, dorsal root entry zone.

(CO₂) laser to vaporize the fat because it chars the surface and thus blurs the safety net of the white plane, and because of its hands-off nature, it does not provide the tactile feedback of the microscissors, on which the surgeon depends to differentiate between clipping the slight grittiness of fibrous fat, the tougher white plane, and the formless softness of the spinal cord. The neodymium:yttrium–aluminum–garnet (Nd:YAG) laser may produce slightly less blackening of the target surface but is hardly better in navigating the dissection plane, and it also lacks contact feedback. Bleeding on the white plane can be handled with the ultrafine irrigating bipolar cautery (0.2-mm tips) and a very low current setting. The cold irrigation mitigates against sticking, but more importantly, it dissipates heat rapidly from the cord. Minimal diathermy is used on the DREZ to avoid post-operative dysesthesia.

As long as all the activities are carried out medial to the fusion line, and thus also medial to the DREZ and nerve roots, dissection along the white plane can be conducted safely all the way to the end with no damage to the cord or nerve roots (► Fig. 26.18 and ► Fig. 26.19). In a dorsal lipoma, this is a simple feat because the white plane is basically horizontal and flat, the two banks are symmetrical, and the caudal end is well defined rostral to the conus, so that a completely circumscribed attack on the fat is possible from multiple angles (► Fig. 26.20). In a large transitional lipoma, navigating the white plane is more difficult because it always slopes ventrally and often undulates, and one side may be tilted so steeply that the corresponding DREZ and nerve roots are shifted ventrally and the placode so rotated that its ventral surface now faces the side. Such a white plane is almost turned vertically “on edge,” and its orientation is confusing unless one remembers the transverse line concept of dividing a “clean” ventral hemisphere from a “messy” dorsal one.

The white plane sometimes seems to be never-ending in large transitional lipomas, and the caudal thecal sac is thronged with fat admixed with suspicious strands. This is when systematic stimulation and identification of the ventral nerve roots become invaluable in localizing the termination of the *functional* spinal cord. The S2 ventral root is readily identified when both the anal sphincter and the abductor hallucis contract on appli-

Fig. 26.20 A dorsal lipoma can be resected with a completely circumscribed perspective from all sides of the fusion line.

cation of a low current of 0.3 to 1.0 milliamperes, and the next two sets of caudal rootlets with a “pure” sphincter response are thus S3 and S4. As soon as these sphincter roots are found and preserved, the tissue distal to the last “live” pair can be considered nonessential and can be cleanly cut across to achieve the final liberation of the placode (► Fig. 26.21b). A good chunk of the now isolated distal fatty stump should be excised to prevent reconnection with the terminal placode.

In chaotic lipomas, electrophysiologic determination of the functional extent of the neural placode may be the only way to achieve final untethering; the caudal fat–cord–fibrous jumble can be sorted out only functionally and not anatomically, by direct stimulation of the placode and the projecting nerve roots. The handling of the white plane on the dorsal side of a chaotic lipoma is the same as with the other lipoma types, but the billows of fat on the ventral side of the placode should be left alone and its smooth pial surface left unviolated (► Fig. 26.21). It is always the dorsal and never the ventral part (unless iatrogenically invaded) of the lipoma that actually tethers the spinal cord.²

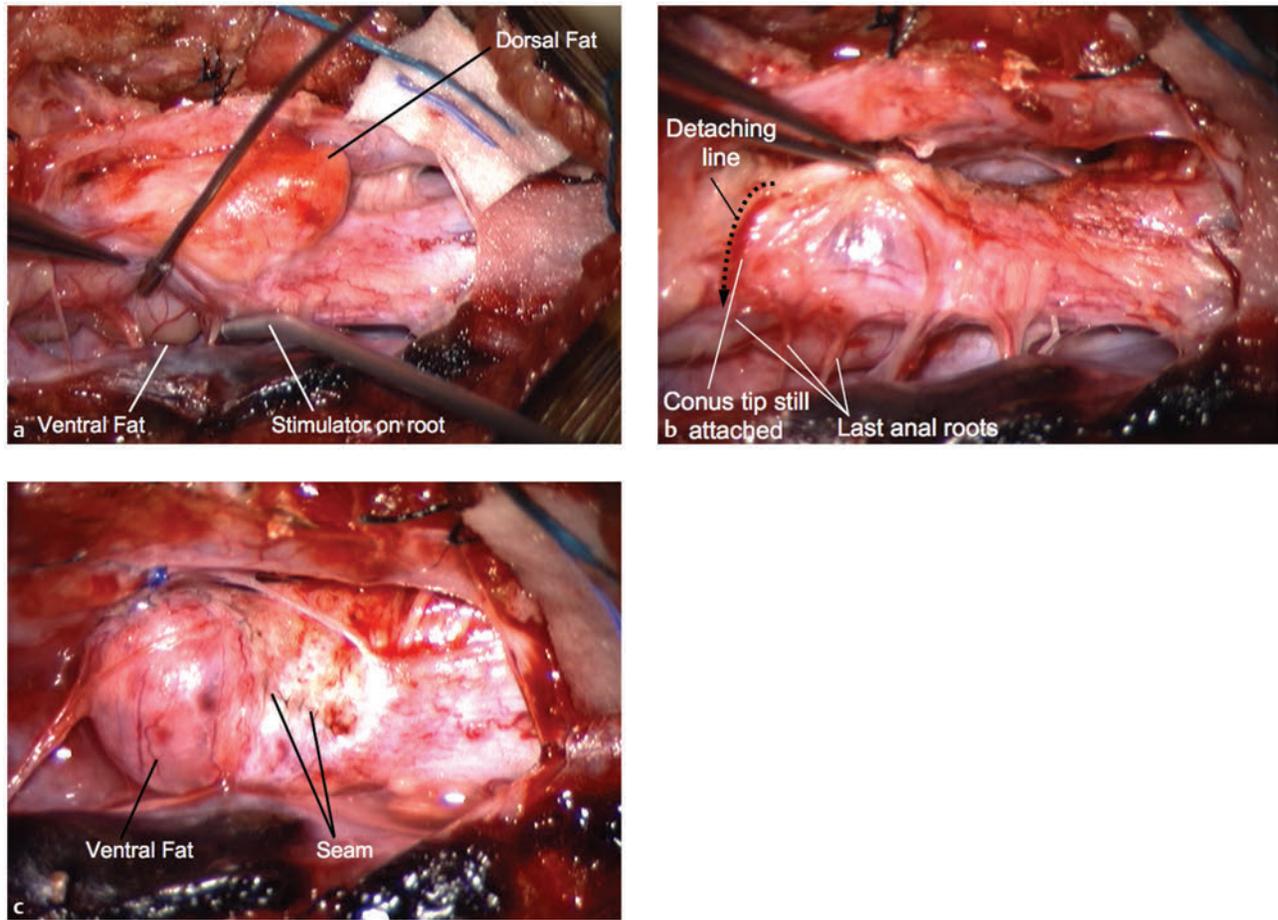

Fig. 26.21 Chaotic lipoma. (a) Note the ventral pia-covered fat medial to the ventral nerve roots (being stimulated by the concentric microprobe) and the dorsal fat located on the dorsal side of the placode. (b) Terminal disconnection of the neural placode from the residual caudal lipoma stump after identification of three healthy pairs of anal sphincter motor roots. (c) Caudal placode pulled up dorsally widthwise, to be neurulated with the more proximal pial edge to form the seam, displaying the unviolated pia-covered ventral fat as a blunt stump.

26.4.4 Step 4. Neurulation of the Neural Placode

Total resection of the dorsal fat and thorough unhinging of the placode convert a bulky, transfixated lipoma–cord complex into a free-floating, thin, supple, purely neural plate (► Fig. 26.19), eminently suitable for pia-to-pia, midline dorsal closure with interrupted 8-0 nylon sutures without strain or strangulation to the neural tissue (► Fig. 26.22a). It is helpful to leave a narrow cuff of pia along the cut edges of the white plane to accommodate the sutures, which are tied with inverted knots. Neurulation thus transforms a broad, waferlike, sticky sheet into a trim, sturdy, pia-covered tube bearing a single seam, evocative of the natural neurulation process (► Fig. 26.22b).

26.4.5 Step 5. Expansile Graft Duraplasty

The argument for a graft dural closure comes from the belief that if the neurulated placode could slosh about in ample CSF

within a capacious sac, the likelihood of reattachment to the dura would be diminished. The choice of graft material is based on two important criteria: its texture and its propensity to leak CSF at the suture holes. Gore-Tex (W. L. Gore, Newark, DE) is too stiff for infant dura and leaks badly, so it was discarded in our early trials. CSF also regularly oozes through DuraGen (Integra, Plainsboro, NJ). Autologous fascia lata, once a popular option, is so soft and pliant that it swells and ebbs with respiration and body movements, and during its in-phase it almost completely collapses onto the neural placode. Thus, we prefer the slightly full-bodied yet texturally compatible (with infant dura) bovine pericardium (Dura-Guard; Synovis, St. Paul, MN), which can maintain a “puffed-up” shape at all times and does not leak. A close second choice is Durepair (Medtronic Neurologic Technologies, Goleta, CA), which is made of reconstituted collagen matrix from bovine skin rather than straight bovine pericardium; it is only slightly stiffer than Dura-Guard and also does not leak at suture holes. The bovine graft is carefully measured and shaped to prevent inward folds. Running Prolene sutures are used to achieve a watertight closure, which is confirmed with Valsalva maneuvers (► Fig. 26.23).

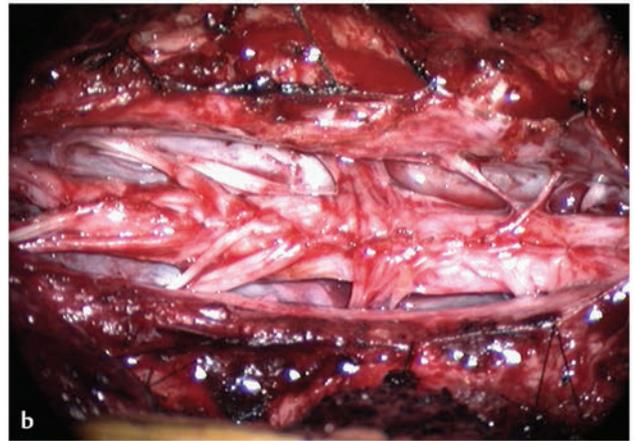

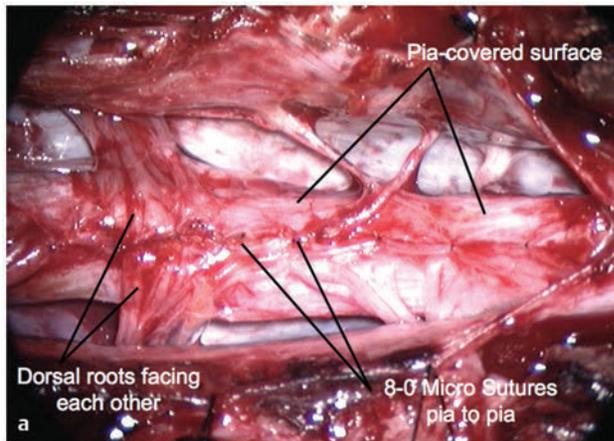

Fig. 26.22 Step 4 of surgical technique. (a) Pia-to-pia neurulation with 8-0 nylon sutures tied with inverted knots. Reconstituted neural tube is now completely covered with pia, and the dorsal root entry zones on each side are once again facing their opposite counterparts near the midline. 26.5 Technical Points

Our data show that a total or near-total resection of spinal cord lipomas can be done in more than 90% of cases² (► Fig. 26.24). In most instances, a small amount of residual fat is adherent to the DREZ and has been invaginated out of mischief during neurulation (► Fig. 26.25). In the 8% of patients with an unusually large amount of residual fat, the fat belongs to the ventral component of a chaotic lipoma and has been intentionally left pia-covered and therefore harmless.

To assess the “looseness” or degree of freedom of the reconstructed placode within the newly formed dural sac, we created the cord–sac ratio, defined as the ratio of the diameter of the cord to the diameter of the sac on the postoperative axial MRI at the bulkiest portion of the reconstructed segment. The ratios are classified as low (<30%) in the loosest sacs, medium (30 to 50%) in moderately loose sacs, and high (>50%) in the tightest sacs (► Fig. 26.26). In the total group of 238 patients, 162 (68%) had low cord–sac ratios, 61 (25.6%) had medium ratios, and 15 (6.3%) had high ratios.²

The size of the lipoma is not an important determinant of the completeness of resection. Much more relevant is the

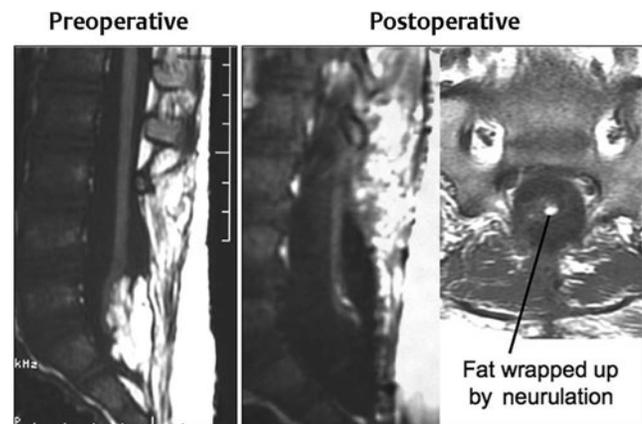

Fig. 26.25 Pre- and postoperative magnetic resonance images of a case of complex transitional lipoma with a very small amount (<20 mm³) of residual fat after resection. Axial image shows the small round piece of fat wrapped up within the roundly neurulated neural placode and therefore not exposed on the surface.

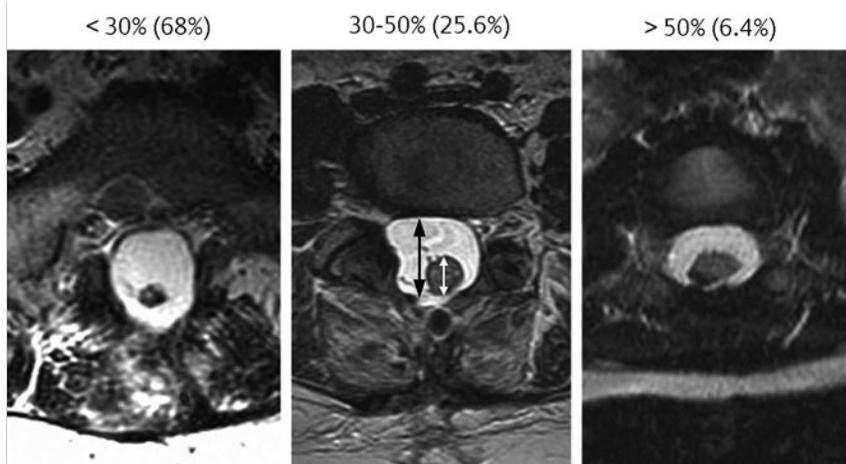

Fig. 26.26 Cord-sac ratios on the postoperative axial magnetic resonance images after total or near-total resection of lipoma. This ratio is obtained by dividing the sagittal diameter of the most bulbous portion of the post-neurulated neural placode by the sagittal diameter of the dural sac. In our series, 68% of the patients had very loose sacs (cord-sac ratios <30%), 25.6% had intermediate ratios (30 to 50%), and 6.4% had high ratios (>50%), with the least commodious cord-sac relationship. The cord-sac ratio estimates the degree of freedom of motion of the post-neurulated spinal cord within its container sac.

configuration of the lipoma-cord interface, which contains the “white plane.” The white plane is a filmy netting of relatively compact collagen fibers. It may be extremely contorted and asymmetric in some transitional lesions, and there is no better way than boldly cutting into the tongue of the rostral lipoma to find the glistening fibers beneath the first few globules of yellow fat. Once the plane is located, one can follow it with sharp dissection by feeling the grittiness through the microscissors and by spotting the glistening white stripes between yellow fat and pink spinal cord. With large dorsolateral transitional lipomas, the placode may be twisted 90 degrees, and the lipoma-cord interface can look almost vertical. Access to the DREZ of the ventral (down) side can be awkward unless the “hammock” is first unhinged and the placode is swung back to a more horizontal position. On the more involved side, festoons of overhanging fat may obscure the emerging dorsal roots to give the false impression that they *course through*, not underneath, the lipoma. In fact, this overhang can be readily teased and lifted off the “knee turn” of the dorsal rootlets to allow these to be traced under the veranda of fat into the true DREZ, at which site the white plane can once again be picked up. In general, a sinuous and severely rotated white plane makes it more likely that residual fat will be left behind.

Redo lesions are associated with a higher rate of residual fat and a higher cord-sac ratio. When the fat layer is infiltrated by a heavy cicatrix from previous surgery, the cementing hold to the surrounding dura is much more tenacious and harder to detach, and the bright yellow of “virgin” fat is lost to a gray, dense concretion that is much harder to distinguish from the white plane. The dissection is often stopped short of the white plane for fear of cutting too deep, and the result is a stiffer slab of residual scar-studded fat that not only augments the bulk of the placode, but also makes it awkward to fold at neurulation. The presence of this unyielding fat and scar at the DREZ often leads to “gouging,” which may well be the cause of postoperative dysesthetic pain in patients.¹

Incomplete terminal untethering of the placode predictably ends in a recurrence of symptoms.⁴²⁻⁴⁴ We ascribe two explanations for the surgeon’s hesitation to make the final disconnecting cut. With very large transitional lipomas, the distal neural placode is buried in fat, and unless visualization is improved by the substantial removal of fat, safe untethering cannot be done.

Also, nerve twigs are sometimes seen issuing in pairs from the distal placode, making it seem impossible to complete the detachment without sacrificing functional cord. This assumption is spurious, for as long as two or three anal sphincter-activating roots, presumably S2 to S4, are identified and preserved, there should be no loss of function if the terminal cut is made just *caudal* to these roots. The small nerve twigs within the discarded stump that do not respond to stimulation are probably coccygeal roots; these are vestigial in humans and have no essential function.^{1,2,45}

Thus, thorough lipoma and scar resection and terminal untethering impart the optimal bulk, texture, and maneuverability to the neural placode for tensionless neurulation. A low postoperative cord-sac ratio has been shown to be the single most important factor in securing a long-term progression-free survival (PFS) in lipoma surgery¹ (see below).

Finally, our experience unequivocally shows that chaotic lipomas are the most treacherous lesions. They can be recognized on preoperative MR imaging by the presence of ventral fat medial to the ventral nerve roots and by their association with sacral agenesis (► Fig. 26.21). Compared with other lipoma types, chaotic lipomas are more likely to show conspicuous residual fat and a high cord-sac ratio on postoperative MR imaging.^{1,2} The strategy for a chaotic lesion is knowing just when to stop excavating deeper after the dorsal portion of the lipoma has been removed to enable neurulation. If the ventral fat is judged not amenable to total excision and neurulation, then its pial surface that had hitherto lain freely against the adjacent ventral dura should be left untouched to avoid creating new adhesions (► Fig. 26.21c).

26.6 Complications

Our combined neurologic-urologic deterioration rate following total or near-total resection is 4.2%, which compares favorably with rates in the literature ranging from 0.6 to 10%^{5,6,44,46-59} and averaging 3 to 7%, associated with partial resection using more conservative techniques for partial resection. Only 1.7% of patients had new weakness, but about 4% had neuropathic pain, which, we suspect, was due to close encounters of the DREZ and dorsal roots with heat from the electrocautery. Most minor

bleeding on the cord can be stopped with gentle tamponade and Gelfoam, and if diathermy has to be applied, only the ultra-fine microtipped irrigating bipolar cautery should be used, with very low current intensity.

The CSF leak rate (0.8%) and wound complication rate (1.3%) with total resection are much lower than in almost all of the published series (of partial resections), which record CSF leak rates from 2 to 47%^{6,44,47,48,52–54,57,59} and wound dehiscence and infection rates of 2 to 26%,^{6,44,48,50,52,54,57,59} Good results can be attributed to the following technical stipulations: (1) Enough bony exposure must be done caudally so that a cuff of healthy dura *past* the lowest extent of the lipoma can be made available for graft anastomosis. The graft should never be sewn to the web of fat at the remaining lipoma stump. (2) Absolutely watertight closure of the graft with Prolene must be achieved and tested with Valsalva maneuvers. (3) Synthetic or organic tissue glues are used if there is even a suggestion of a leak. (4) In large sacral lesions, there are often gaping muscle and fascial defects that cannot be primarily approximated. In these cases, paramedian relaxing incisions can be used on the flanking lumbodorsal fascia to facilitate sliding midline closure of the myofascial edges.⁶⁰ A large subcutaneous lipoma is never removed at the time of intraspinal surgery. The creation of this immense dead space will encourage the collection of CSF, which may turn into an enlarging pseudomeningocele that compresses the dural graft back onto the cord and prevents the desirable “billowing effect” of CSF on the new thecal sac. A tense pseudomeningocele may even threaten skin flap viability.

26.7 Results of Total Resection

26.7.1 Early Postoperative Results

The early postoperative results were very similar between our total and partial resection groups.¹ For asymptomatic patients in both groups, the rates of neurologic preservation were 98% and 94%, respectively. In symptomatic patients who underwent total or near-total resection, 61% had a normal or improved neurologic status and 33% remained unchanged, thus giving a rate of 94% for improvement or stabilization of disease. In symptomatic patients who underwent partial resection, 33% were improved and 62% had disease stabilization, at least for the short term.

Our early postoperative results for total resection are thus comparable to or better than those in the literature, in which mainly reported partial resection.^{5,44,47,48,54,57,58} In particular, prophylactic total resection of asymptomatic lipomas carries a small neurologic risk when done by experts. Also, the benefits of radical surgery are obvious for patients with progressive deterioration. Finally, early improvement and stabilization rates are almost identical for total and partial resection, suggesting that the immediate benefits of surgery are due to the abrupt relief of traction on the conus and not to the extent of lipoma resection or placode reconstruction. Authors who specifically describe their inability to completely disconnect the conus from its caudal attachment owing to the presence of obscuring residual fat and an undelineated cord–lipoma margin also point out the corresponding poor outcome of these patient.^{6,42,44}

When the postoperative status of patients with total resection is correlated with preoperative symptoms, the best result is seen for pain. Most of the sharp, dysesthetic leg and perineal pain significantly diminishes within 3 months, but not necessarily low back pain, which is likely mechanical in origin.^{61,62} Children also become more active and playful, and virtually never have chronic back complaints. Sensorimotor deficits also respond favorably to surgery. Although fewer than 20% of patients have an actual normalization of motor function, the majority substantially improve.^{1,2} Like patients with other forms of tethered cord, those with milder and more recent deficits have a better chance for a good recovery. Bladder dysfunction responds favorably in about 20 to 30% of patients.² The subtype of neuropathic bladder with the best prognosis is the small-capacity, spastic bladder with uninhibited detrusor contraction. Atonic bladders seldom improve with surgery, and intermittent catheterization usually needs to be continued indefinitely. The response of detrusor–sphincter dyssynergia to surgery is unpredictable. It is mandatory that cystometry and voiding cystourethrography be repeated 3 to 6 months after surgery to determine what other urologic procedures, such as bladder augmentation and placement of ureteral conduits, may be necessary to prevent reflux and frequent infections. Surgery has been known to arrest the rapid worsening of existing scoliosis in patients with a tethered cord. However, severe scoliosis still requires surgical realignment and fixation with instrumentation and fusion.

26.7.2 Long-term Outcome

Whereas the *immediate* benefits of total lipoma resection are due to the abrupt cessation of spinal cord tethering and are thus comparable to those of partial resection,² the long-term advantage of total over partial resection becomes very obvious if the PFS of the two techniques are calculated for periods of 15 to 16 years. The PFS after total resection for all lipoma types and clinical subgroups is 84%, versus 34% for partial resection.¹ The differences in PFS are even more marked when the lipomas in each treatment group are segregated according to presence or absence of symptoms, patient age, and whether previous surgery was done.¹ The risk for symptomatic recurrence is 5.94 times higher after partial resection than after total or near-total resection over 12 years by the Cox proportional hazard regression model ($p < 0.00001$; ► Fig. 26.27). Even though the comparison is between prospective and retrospective data, the impressive difference in long-term PFS between the two techniques makes a compelling argument for endorsing total or near-total over partial resection.

The question is often asked whether surgery should be offered to children with asymptomatic lipomas. In 2004, a prospective study of the nonsurgical management of asymptomatic lipomas from l'hôpital Necker-Enfants malades, Paris,⁶³ reported an actuarial risk for deterioration of 40% over 9 years, with a PFS probability of 60%.⁶⁴ Given that children with lipomas have an actuarial life of 65 to 70 years, and given further that established neuropathic bladder and sensorimotor deficits seldom fully recover following *post factum* or salvage surgery,^{2, 5,28,39,62,66} the endorsement for prophylactic surgery seems attractive if it does in fact offer clear outcome advantage over conservative treatment.

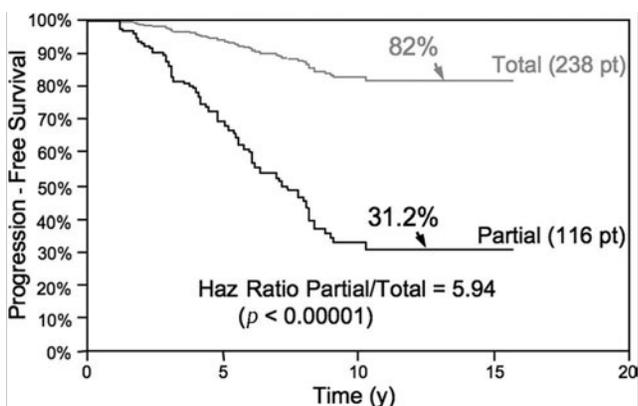

Fig. 26.27 Cox proportional hazard regression analysis of long-term outcome of total versus partial resection of lipomas.¹ Progression-free probabilities for the two treatment groups are indicated by arrows. The hazard ratio for symptomatic recurrence of partial to total is 5.94 ($p < 0.00001$). The advantage of total over partial resection is obvious. pt, patients; Haz, hazard; Partial and Total indicate extent of resection.

When the select group of young children without symptoms or prior lipoma surgery from our total resection series is put up against the Parisian series, the superiority of total resection is obvious, with a 16-year PFS of 98.4%¹ compared to 67% for conservative management⁶³ (► Fig. 26.28). Furthermore, there is a strong suggestion of stabilization of disease 5 years after total resection, whereas the probability of deterioration remains cumulative beyond 9 years with nonsurgical treatment.⁶³ These robust statistics argue strongly for total resection, not only for symptomatic patients but also as prophylactic treatment for all comers.

There are currently no longitudinal data on untreated asymptomatic lipomas in adults, and the actuarial life span for adults is obviously shorter, so a forceful argument cannot be made for prophylactic surgery in adults with lipomas. When a lipoma causes symptoms, however, it is widely assumed that deterioration will be inexorable, and aggressive surgery can be justified regardless of the patient’s age.

26.8 Cord–Sac Ratio and the Importance of Neurulation

Comparing our two series of total and partial lipoma resections, we found a steep bias for low cord–sac ratios with total resection, making cord–sac ratio the most likely factor that differentiates total from partial resection. That a low cord–sac ratio is an extremely important determinant of good outcome is amply supported by the Cox multivariate model, which shows that the cord–sac ratio exerts a highly significant, independent influence on outcome. This means that no matter how the associative influences of age, symptoms, lipoma type, and prior surgery reinforce or cancel one another, the influence of the cord–sac ratio stands solitary and undiminished (► Fig. 26.29). Thus, all other variables notwithstanding, a cord–sac ratio higher than 50% predicts a 5.6 times greater risk for disease progression than does a low cord–sac ratio of less than 30%, with a high statistical significance (► Fig. 26.30).

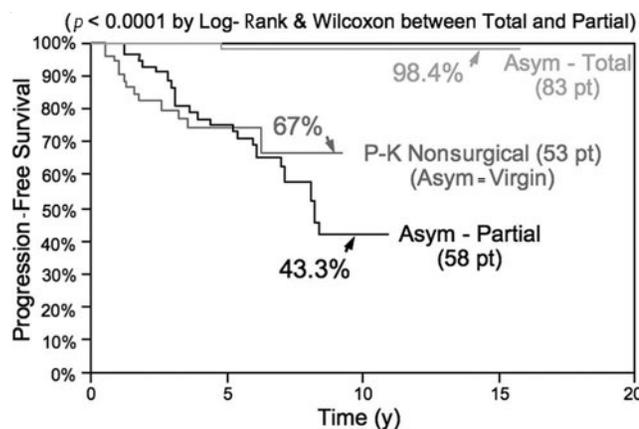

Fig. 26.28 Outcome differences between total resection, partial resection, and nonsurgical management of asymptomatic virgin lipomas by Kaplan-Meier analysis.¹ The nonsurgical survival function graph (P-K [Pierre-Kahn] Nonsurgical) from the Parisian study⁶³ is inserted for visual comparison only and is not meant to imply a true head-to-head comparison. Progression-free probability at 16 years for the 83 asymptomatic virgin lipomas that underwent total resection is 98.4%, much better than the 67% in the Parisian series and far superior to the 43.3% in our own partial resection series. The difference between total and partial resection for asymptomatic virgin lipomas is highly significant ($p < 0.0001$). pt, patients; Asym - Total, asymptomatic virgin lipomas treated by total resection; Asym - Partial, asymptomatic virgin lipomas treated by partial resection; P-K Nonsurgical (Asym - Virgin), asymptomatic virgin lipomas managed nonsurgically.⁶³

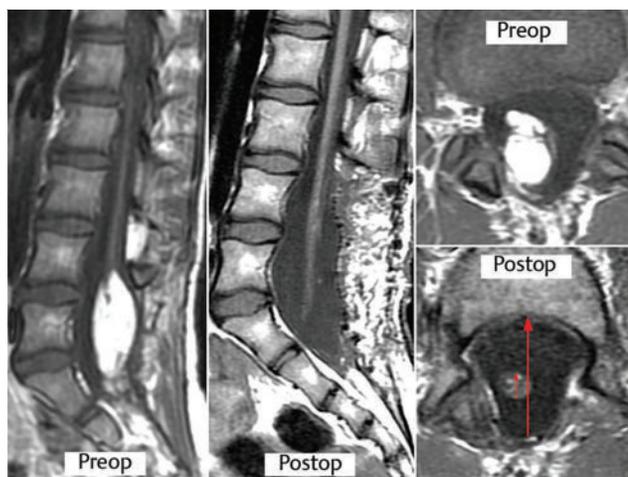

Fig. 26.29 The pre- and postoperative sagittal and axial magnetic resonance images of a 10-year-old girl who had undergone two previous partial resections of a large transitional lipoma and who was also highly symptomatic. The achieved postoperative cord–sac ratio was 20% (lower right), and she enjoyed long-term progression-free status.

In an operational sense, the cord–sac ratio may be thought of as the summated product of the other predictors. For example, previous surgery on the lipoma undoubtedly makes it much harder to achieve a small cord–sac ratio; the texture and hue of scar tissue within the fat can be confused with the white plane, leading to retention of excessive fat and cicatrix and a bulky

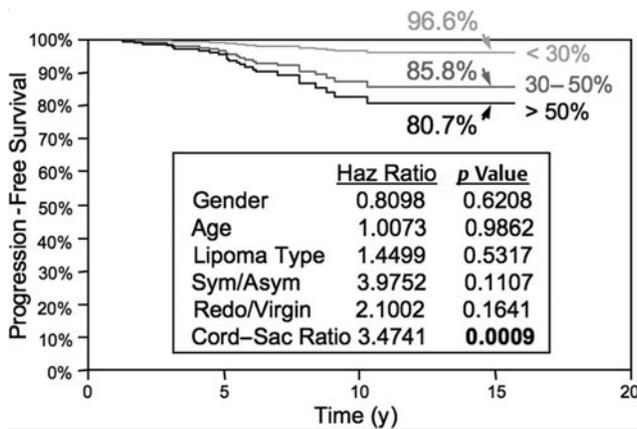

Fig. 26.30 Cox multivariate proportional hazard regression model analyzing the combined influence of six predictor variables (gender, age, lipoma type, symptoms, redo vs. virgin, and cord-sac ratio) on progression-free survival after total resection, featuring the resultant effect of the three cord-sac ratios of < 30%, 30 to 50%, and > 50%.¹ The hazard ratios and *p* values for all six predictor variables are listed in the miniaturized table, which shows that the cord-sac ratio exerts the only significant independent influence on outcome. The respective progression-free probabilities, indicated by the arrows, are 96.6% for low ratio, 85.8% for intermediate ratio, and 80.7% for high ratio. The differences in hazard prediction for the three ratios are highly significant (*p* = 0.0009, in boldface type). The ratios of < 30% to 50%, and > 50% indicate the three cord-sac ratios mentioned. Sym/Asym, symptomatic versus asymptomatic lipomas.

placode.² Since many of the symptomatic lipomas in our total resection group are redo lesions, their poor prognosis may in large part be due to the pre-eminence of the “redo factor.” This “redo factor” is likely also the underlying cause for the negative effect of age on outcome because older patients are more likely to be symptomatic and to harbor redo lesions.

Although a loose-fitting sac permits a greater freedom of cord motion within the CSF and is proven important in preventing retethering, adhesion to the dura can still happen if what remains exposed is a sticky, unneurulated, raw lipoma bed. Meticulous neurulation conceals this raw surface within an imbricated seam. Our experience of re-exploring unneurulated placodes leaves no doubt that this raw surface is a conspicuous focus of adhesion to the dura much more than a well-executed seam. Though not an easily quantifiable act, concealment of this adhesive surface through minutely careful neurulation must rank equally with a low cord-sac ratio as staunch insurance against retethering.

26.9 Is Partial Resection Worse than No Resection?

This is a prickly question because an affirmative answer seems self-serving in the present context, yet it would be disingenuous to ignore the fact that our results for partial resection of 116 lipomas^{1,2} are clearly worse than those in the Parisian series⁵⁴ of nonsurgical treatment. Even if we select only our asymptomatic patients, which in essence eliminates all the surgically more treacherous redo lesions, the PFS for partial resection is still only

43% at 11 years,¹ compared with 67% in the nonsurgical series⁶³ (► Fig. 26.28). Other series of partial resection do not fare much better. If the terminal lipomas were excluded, the series of Colak et al⁶⁵ would have a PFS rate of less than 50%, and the series of partial resection of Pierre-Kahn et al would have a PFS also lower than 40%.⁶ The transitional lesions of Cochrane et al⁴⁷ had only a 20% PFS over 10 years, and Cornette et al⁶⁶ reported a rapid progression of symptoms after partial resection.

We were impressed, after having tackled more than 100 redo lipomas, that a once-abraded but unneurulated placode can be much more firmly fused to the dura by unyielding scar than an unchastened lipoma stalk. If the likelihood of deterioration has to do with the rigidity of transfixation of the cord, one would anticipate partial resection to incur earlier and perhaps worse recurrence than if no surgery had been done. It would also explain why partial resection typically provides instantaneous relief of symptoms due to the *initial* untethering, but is unable to sustain this effect in the long run because of delayed scar formation. Ultimately, the patient experiences an increasingly failing course that compares poorly with the natural history of the disease.

26.10 Conclusion

The total or near-total resection of complex spinal cord lipomas and complete reconstruction of the neural placode produce a much better long-term PFS than partial resection. In comparing our own statistics with published data, we also found that total or near-total resection confers significantly greater benefits than nonsurgical management in the subset of patients with asymptomatic virgin lipomas. The postoperative rates of neurologic, urologic, and wound complications after total or near-total resection are either comparable to or much lower than those in other series reporting on partial resection.

Multivariate analyses show that a low postoperative cord-sac ratio and a well-executed neurulation of the neural placode are strongly correlated with a good long-term outcome. The ideal patient profile for early disease stabilization and the best recurrence-free survival has been identified to be a child younger than 2 years of age who is without symptoms or a history of previous surgery.

Based more on experience than on hard statistics is the impression that chaotic lipomas are the most difficult lesions to resect and may ultimately prove to be the most problematic type of lipoma. Also, there are strong indications that partial resection in some cases produces severe scarring at the lipoma-cord interface, which may actually worsen prognosis than if no surgery is done.

As a coda, I feel obliged to deal with the unceasing murmur that radical lipoma resection is too difficult and unlearnable. I suspect that the word *radical* may have an intimidating connotation that unintentionally deters attempts to explore even the basic brushwork. In truth, and as many observers of the operation can attest, a few specific maneuvers of total resection may be novel, but the fundamental microsurgical techniques are those taught in any modern neurosurgical program. In addition, the essential electrophysiology can be mastered by any trained neurophysiologist, and the monitoring hardware can be purchased at reasonable cost. Perfecting the procedure admittedly

takes arduous practice, but so does everything else in neurosurgery. Success in this endeavor ultimately depends more on a singularity of mind and granite tenacity, practicable by most, than on the sort of rarified technical wizardry inculcated by proponents of other revolutionary surgery.

Pearls

- Total or near-total resection of complex spinal cord lipomas and radical reconstruction of the neural placode can be done safely if one respects a few unique anatomical features and adheres to specific surgical principles.
- The long-term retethering-free probability for all lipoma types is much higher with total resection than with partial resection. Success is also strongly correlated with the postoperative cord–sac ratio and the state of neurulation of the neural placode.
- The long-term prognosis of total resection for the subset of children with asymptomatic virgin lipomas also far surpasses that of partial resection and the natural history of the disease. Total resection is recommended as prophylactic treatment for this subgroup.
- Partial resection has a much worse long-term outcome than no surgery for asymptomatic lipomas because of the creation of new scarring that causes more staunch tethering.
- Intraoperative electrophysiologic monitoring is an essential adjunct, especially for children who have large and complex lipomas with seemingly unending caudal involvement with fibrofatty tissue.
- The surgical and intraoperative physiologic monitoring techniques can be readily learned by anyone willing to do so, and the hardware can be purchased at a reasonable cost.
- Chaotic lipomas emerge as a small but problematic subset whose treatment demands special skill and perspective.

27 Craniovertebral Junction

Arnold H. Menezes and Raheel Ahmed

A wide spectrum of congenital, developmental, and acquired abnormalities arises at the craniovertebral junction. These abnormalities are due to a complex developmental anatomy and to the neuroanatomical and musculoskeletal transitions between the brain and spinal cord and between the skull and cervical spine, respectively. Various craniovertebral pathologic conditions involve the osseous structures and encompassed neurovascular system, resulting in a constellation of signs and symptoms that often complicates diagnosis in children.^{1,2}

Historically, craniovertebral abnormalities have been defined through autopsy reports, followed by anatomical and embryologic studies and much later by radiographic imaging.³ Initial surgical treatments consisted of posterior decompression combined with occasional dorsal fusion. Advances in neurodiagnostic imaging and microsurgical instrumentation have improved our understanding of the biomechanical properties of this complex region and have enabled the effective treatment of a wider range of pathologic entities.^{2,4,5} Nonetheless, surgery at the craniovertebral junction is still considered a neurosurgical quagmire because of the associated high morbidity and mortality. In 1977, the senior author (A.H.M.) proposed a surgical physiologic approach to the treatment of abnormalities at the craniovertebral junction in children, based on an understanding of the dynamics, stability of the craniovertebral region, site of encroachment, and associated neural abnormalities.⁶ Since then, more than 6,000 pediatric and adult patients with various craniovertebral disorders have been evaluated at the hospitals and clinics of the University of Iowa. More than 1,900 of these bony abnormalities occurred in children younger than 16 years of age. This experience has helped define the natural history and the anatomical, biomechanical, and embryologic basis of craniovertebral pathology, and this knowledge in turn has led to an improved understanding and treatment of these complex disorders.

27.1 Relevant Anatomy and Biomechanics

The occipitoatlantoaxial complex is the most mobile and complex joint of the axial skeleton.² Flexion and extension occur at the occipitoatlantal and the atlantoaxial articulations (► Fig. 27.1a,b). In children, the anteroposterior translation between the anterior arch of atlas and dens, the “predental space,” can be up to 5 mm until the age of 8 years and should be less than 3 mm in adults.^{2,7,8} Cervical rotation occurs primarily at the atlantoaxial joint. Atlantoaxial rotation beyond 35 degrees is associated with a risk for contralateral vertebral artery injury.⁴ Further rotation exceeding 45 degrees is associated with facet interlock between the atlas and axis vertebrae (► Fig. 27.2 a–g). This has particular significance in atlas assimilation, for children participating in contact sports, and for those who undergo excessive rotation of the head during general anesthesia or forceful head manipulations. The absence of uncovertebral joints as well as the horizontal orientation of facets in children also raise the risk for upper cervical injury.

The cervical paraspinal musculature and ligamentous complex impart stability to the craniovertebral articulation and also form the pathogenic basis of various craniovertebral junction anomalies.^{2,9} The most critical craniovertebral ligament is the transverse ligament, which maintains mechanical stability of the atlantoaxial joint complex.¹⁰ It allows atlantoaxial rotation up to 47 degrees while preventing anterior subluxation of C1 on C2. The alar ligaments extend from the basion to the axis and serve to secondarily stabilize the C1–C2 joint and prevent extreme axial lateral rotation beyond 90 degrees.¹⁰ Alar ligamentous injury is typically associated with whiplash injuries. With disruption of the cruciate ligament, the load is then placed on the alar and the apical ligaments, which quickly become incompetent.⁷

(d) Three-dimensional reconstructed image indicates the abnormal bony configuration. A, anterior; P, posterior. (e) Axial T2-weighted image indicates rotation of C1 on axis with a torn cruciate ligament (arrow). (f) Axial T2-weighted image in another patient indicates increased signal intensity within the alar ligament, adjacent to the odontoid (arrow). (g) Coronal T2-weighted image indicates the presence of a torn alar ligament (arrow) in the same patient.

Lymphatic drainage of the occipitoatlantoaxial joints is primarily through retropharyngeal nodes into the deep upper cervical lymphatic chain. These nodes also drain the nasopharynx, retropharyngeal area, and paranasal sinuses.^{2,11–14} Hence, a retrograde inflammatory change may affect the synovial lining of the craniocervical joint complex, with resultant effusion, instability, and subsequent possible neurologic deficit. This has been referred to as Grisel syndrome.¹¹ The atlantoaxial joints are the most vulnerable and affected in majority of patients. In addition, the periodontal venous plexus and suboccipital epidural sinuses communicate with the pharyngovertebral veins. This can result in osteomyelitis of the craniocervical joints due to paravertebral infections.¹³

The vertebral and the occipital arteries provide blood supply to the craniocervical region.¹³ The vertebral arteries give rise to anterior and posterior ascending branches that anastomose in an apical arcade and supply small perforating branches to the axis body and odontoid process.¹⁵ In addition, ascending anterior branches receive contributions from the carotid arteries. The cartilaginous plate between the dens and axis body prevents the development of a vascular communication between the axis

and its odontoid process. This accounts for formation of a sequestrum in type 2 odontoid fractures and the development of os odontoideum.² Cervicomedullary pathology may also present with false localizing symptoms due to medullary decussation at the foramen magnum and secondary involvement of the lower cervical cord segments due to venous stasis resulting from extramedullary compression of the cervicomedullary junction.⁵

27.2 Classification of Craniovertebral Junction Abnormalities

Craniovertebral anomalies are typically developmental disorders of the cartilaginous neurocranium and adjacent vertebral skeleton.¹⁶ In addition, a wide variety of congenital, hereditary, and acquired anomalies may exist either individually or in combination (see box “Classification of Craniovertebral Anomalies (p.344)”).

Classification of Craniovertebral Anomalies

- Congenital anomalies and malformations
 - Occipital sclerotome malformations: proatlas remnants, clavus segmentations, condylar hypoplasia, atlas assimilation
 - Atlas malformations: bifid atlas, assimilation, fusions, absent arches
 - Axis malformations: segmentation defects, odontoid dysplasias
- Developmental and acquired abnormalities
 - Foramen magnum abnormalities
 - Foramen stenosis: achondroplasia
 - Secondary invagination: osteogenesis imperfecta, Hadju-Cheney syndrome, renal rickets, Paget disease
 - Atlantoaxial instability
 - Down syndrome
 - Errors of metabolism: Morquio syndrome, Hurler syndrome
 - Infections: Grisel syndrome, tuberculosis
 - Trauma
 - Inflammation: regional ileitis, juvenile rheumatoid arthritis, Reiter syndrome
 - Tumors: osteoblastoma, eosinophilic granuloma, chordoma, neurofibromatosis
 - Miscellaneous: Conradi syndrome, fetal warfarin, syringomyelia

Signs and Symptoms of Craniovertebral Anomalies: Insidious or Rapid Onset of Symptoms and Signs

- Head tilt
- Short neck, low hairline, limitation of neck motion
- Web neck
- Scoliosis
- Features of skeletal dysplasias
- Neck pain and posterior occipital headache
- Basilar migraine
- Hand or foot isolated weakness
- Quadriparesis/paraparesis/monoparesis
- Sensory abnormalities
- Nystagmus, usually downbeat and lateral gaze
- Sleep apnea
- Repeated episodes of aspiration pneumonia, dysphagia
- Tinnitus and hearing loss
- Vertigo

27.3 Epidemiology

Underlying craniovertebral anomalies must be suspected in infants with skeletal dysplasias and syndromic disorders like Goldenhar syndrome and Conradi syndrome.^{17–20} Children with Down syndrome have a 14 to 20% incidence of atlantoaxial instability.^{2,21} In Morquio syndrome, a combination of atlantoaxial instability, C2–C3 segmentation failure, os odontoideum, and cervicothoracic abnormalities occurs in 30 to 50% of patients.^{2,21} With an underlying congenital craniocervical anomaly, secondary developmental and acquired phenomena may supervene, producing basilar invagination.²²

27.4 Signs and Symptoms

Craniovertebral disorders present with a constellation of symptoms and signs that reflect dysfunction of the brainstem, cerebellum, cervical spinal cord, cranial nerves, cervical roots, and their associated vascular supply (see box “Signs and Symptoms of Craniovertebral Anomalies: Insidious or Rapid Onset of Symptoms and Signs (p.344)”). The onset may be insidious or rapid, and at times patients may present with false localizing signs. Infrequently, a rapid neurologic progression is followed by sudden death. More commonly, an antecedent history of trauma triggers symptoms that may progress rapidly. The authors feel strongly that children with nasopharyngeal infections and neck spasm (“torticollis”) must be suspected of harboring craniocervical instability unless it is proven otherwise. Temporary bracing and close follow-up with flexion–extension X-rays repeated on a weekly basis will aid in the identification of any underlying instability that can sometimes be masked by muscular spasm in acute presentations.

An abnormal general physical appearance is often seen in children with congenital craniocervical abnormalities. The head may be tilted or cocked to one side in patients with atlantoaxial rotary subluxation or partial segmentation failure. The classic triad of the Klippel-Feil syndrome consists of an abnormally low hairline posteriorly, a short neck, and limitation of neck movement, which may present in conjunction with facial asymmetry and neck webbing.²³ Scoliosis is often present. An abnormal stature and elevated scapula are seen with Sprengel deformity. Systemic skeletal anomalies are typically present, with craniovertebral abnormalities secondary to spondyloepiphyseal dysplasia, achondroplasia, and other types of dwarfism.^{19,24}

Cervical and occipital pain occurs in up to 85% of children and is described as originating in the suboccipital region with radiation to the vertex.^{2,5} “Basilar migraine” occurs in 25% of children affected with basilar invagination and medullary compression and is due to associated compression of the vertebral basilar vessels. Occipitoatlantoaxial instability may cause repeated trauma to the anterior spinal artery and the perforating vessels of upper cervical cord and medulla, leading to vascular spasm or occlusion and secondary neurologic deficits.

The most common neurologic deficit encountered in the 1,700 children in our series was myelopathy. This was equally distributed with motor deficits involving monoparesis, hemiparesis, paraparesis, and quadriparesis. Myelopathy mimicking the “central cord syndrome” was frequently encountered in children with basilar invagination. Similarly, posterior column dysfunction was the most common sensory abnormality. Occasionally, children described an abnormal sensation in their hands or feet. In infants and toddlers, this may be recognized by constant rubbing of the affected limbs. Brainstem and cranial nerve deficits are usually evident by dysphagia and repeated episodes of aspiration pneumonia and sleep apnea. Not uncommonly, internuclear ophthalmoplegia is present, leading to a misdiagnosis of mesencephalic and upper pontine disturbance. Downbeat nystagmus was present more often in patients with an associated Chiari 1 malformation. Unilateral or bilateral paralysis or dysfunction of the soft palate and pharynx leads to repeated bouts of aspiration pneumonia as well as poor feeding

and inability to gain weight. The most common cranial nerve dysfunction was hearing loss in 23% of children and is most commonly associated with Klippel-Feil syndrome. Vascular symptoms, such as intermittent attacks of altered consciousness, transient visual loss, vertigo, and confusion, occurred in 20% of children. At times, this was provoked by cervical extension or rotation or by manipulation of the head and neck.

27.5 Imaging

Plain radiographs of the cervical spine in lateral and anteroposterior views are supplemented by open-mouth and anteroposterior projection views of the foramen magnum.⁸ If instability is suspected, lateral extension and flexion views should be obtained.^{2,5} Several lines of reference have been described to correlate the position of neural structures with the associated osseous abnormality (► Fig. 27.1b).^{3,8} The Chamberlain palato-occipital line joins the hard palate to the posterior edge of the foramen magnum. In a normal individual, the tip of the dens should lie below this line or at most 3 to 5 mm above it.³ When the odontoid process ascends above this line, basilar invagination has occurred. We believe that the Wackenheim clivus-canal line (drawn along the clivus and extrapolated into the cervical spinal canal) is of great significance. The odontoid process must be ventral or tangential to this line under normal conditions, and it transects this line in basilar invagination, atlantoaxial dislocation, and anterior occipitoatlantal dislocation. The McRae foramen magnum line joins the anterior and posterior edges of the foramen magnum, and the tips of the dens must be below this line.¹ A sagittal diameter of less than 20 mm at the cervicomedullary junction is associated with neurologic compromise.²²

Magnetic resonance (MR) imaging aids in an ideal identification of the underlying neural abnormalities and associated osseous compression.^{8,24} Computed tomography (CT) with rapid-acquisition spiral technique and three-dimensional reconstruction is necessary to recognize the presence or absence of epiphyseal growth plates, the extent of fusion, segmentation defects, and “missing” osseous components, especially in infants with torticollis.⁸ In all the techniques of investigation, dynamic flexion–extension studies are necessary for assessing stability and the angular osseous relationships with underlying neural structures (► Fig. 27.3). This also provides information regarding reducibility and the optimal position of fixation if needed.^{2,5} Because of their routine availability, MR imaging and CT angiography have supplanted traditional angiography to identify obstruction or potential occlusion with dynamic positional changes.²

27.6 Surgery

Factors that influence specific treatment are the following: (1) the etiology of the pathologic process (i.e., type of bony abnormality and the presence of Chiari malformation, syrinx, or vascular abnormalities); (2) the reducibility of the bony lesion (ability to restore normal anatomical alignment and relieve compression of the cervicomedullary junction); (3) the mechanics of compression and direction of encroachment; and (4) the presence of abnormal ossification centers and epiphyseal

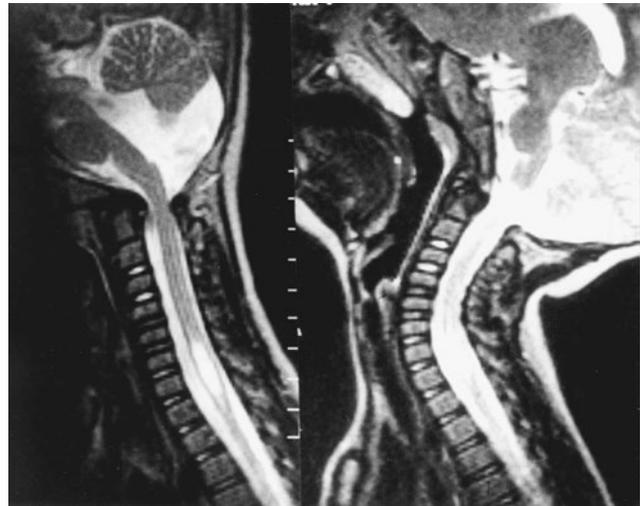

Fig. 27.3 Composite of magnetic resonance imaging of the craniocervical junction in the T2 mode. The flexed position is seen on the left and the extended position on the right. Note the instability at the craniocervical junction. A syrinx is seen in the lower cervical spinal cord.

growth plates.^{2,6} The primary goal underlying surgical treatment is to relieve compression at the craniocervical junction (► Fig. 27.4a–c). In a reducible lesion, stabilization is paramount to maintain neural decompression. Irreducible lesions require decompression at the encroachment site. Ventral lesions require operative approaches through a transpalatopharyngeal decompression, a Le Fort drop-down maxillotomy, or the lateral extrapharyngeal route. Posterior or posterolateral decompression is required for dorsal lesions (► Fig. 27.5). If instability is present after decompression, a posterior fixation is mandatory for stability (► Fig. 27.6a–d).

The management of craniocervical instability in young infants secondary to conditions such as Goldenhar syndrome and osteogenesis imperfecta deserves special mention.² It is essential to determine the potential for osseous development by identifying developing epiphyseal growth plates on thin-section CT. In these instances, we use custom-built cervical orthoses to impart occipitocervical stability while skeletal growth is allowed to occur. During follow-up, the cervical orthoses are replaced periodically and diagnostic studies repeated to monitor the craniocervical region. After adequate bone growth is achieved by 3 to 4 years of age, surgery is undertaken, as described above, if osseous stability has not yet occurred.

Skeletal traction is applied with an MR imaging-compatible crown halo device.^{25,26} In children between 2 and 4 years of age, eight-point fixation is utilized with finger pressure that limits pin pressure to 1 to 1.5 lb of torque. At 5 years of age, 4 lb of maximum pin pressure is utilized. Traction is initiated at 3 to 4 lb and does not exceed 7 lb. Reducible lesions that are the result of inflammatory states or recent trauma will respond to conservative treatment with external immobilization once reduction is achieved. If this does not occur or if the condition is not the result of trauma or infection, surgical fixation is mandated. In children, traction is applied in the operating room under general anesthesia. A cervical collar is used for protection

A previous attempt at dorsal atlantoaxial arthrodesis failed. Instability and an os odontoideum are present. (b) Three-dimensional computed tomography of the craniocervical junction demonstrates the failed dorsal interspinous fusion between C1 and C2. An os odontoideum is present. (c) Postoperative lateral cervical spine and craniocervical radiograph. The halo vest is in place. during intubation maneuvers. After the initial use of general mask anesthesia, fiber-optic intubation is undertaken through the mask. Halo ring traction is then applied during pharmacologic muscle relaxation with general anesthesia. Neurophysiologic monitoring (somatosensory evoked potentials) is maintained during these maneuvers, in addition to image documentation with intraoperative computed tomography with three-dimensional display.²⁷ This is a recent technique developed in the last 4 years. Basilar invagination, craniocervical junction dislocation, and other irreducible states warrant this attempt at “reduction.” It has proved successful in 36 of 52 patients whose abnormalities were felt to be “irreducible.” These patients will not require ventral decompression, but posterior

decompression and stabilization. If surgical fixation is planned simultaneously, an interim clinical assessment is made after reversal of anesthesia while intubation is maintained.

In the case of a grossly unstable but reducible state, a crown halo vest is placed under general anesthesia, and the child is then turned prone on the operating table. The posterior struts are removed to enable dorsal fixation while the ventral struts are maintained for immobilization and to aid postoperative re-application of the halo vest.

In addition to the traditional transoral transpharyngeal surgical approaches, transnasal and transcervical endoscopic techniques have evolved to establish surgical access for the management of irreducible ventral craniocervical lesions.^{28,29} The

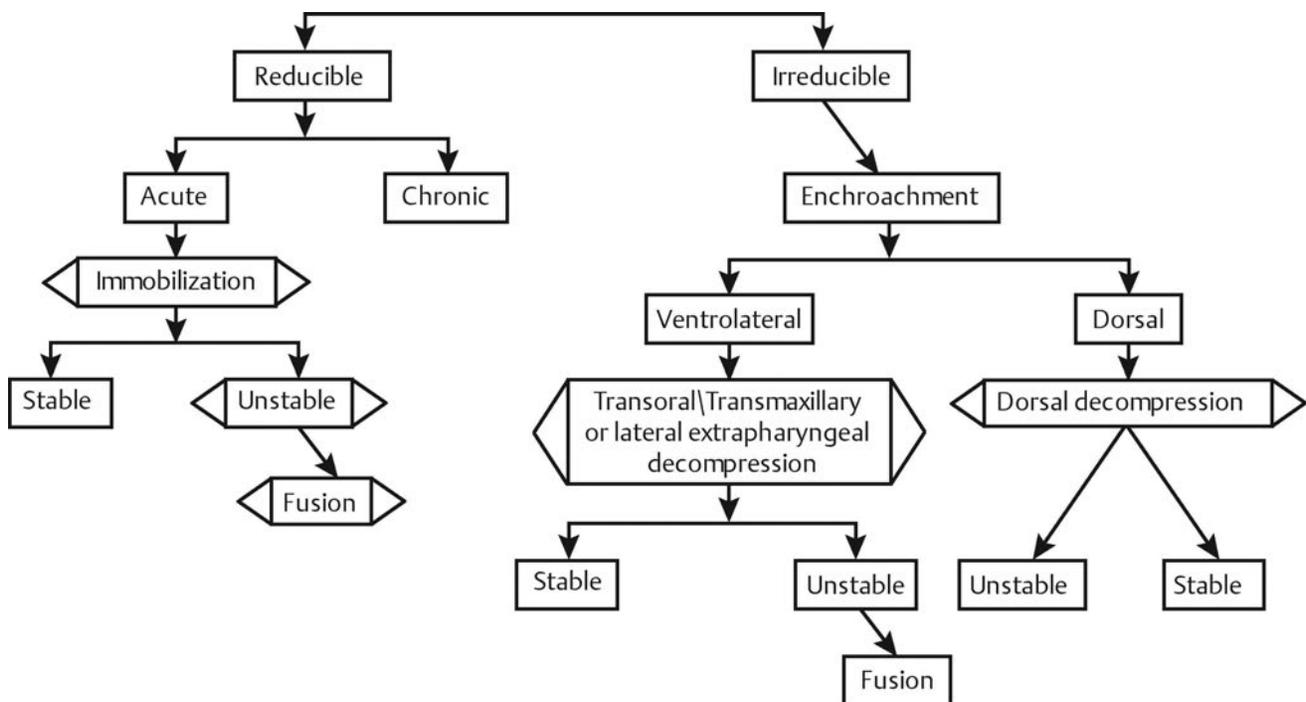

Fig. 27.5 The treatment of craniovertebral abnormalities.

transoral transpharyngeal route offers excellent surgical exposure to address a wide range of ventral craniovertebral junction lesions,³⁰ but it is associated with the surgical morbidity of postoperative dysphagia and the need for postoperative intubation after surgical dissection through the palate and pharynx. The endonasal approach enables access to the rostral craniocervical junction, and it avoids prolonged postoperative intubation and the risk for oropharyngeal dysfunction associated with transoral procedures. Conversely, the surgical access corridor is restricted in the lateral and inferior limits of the exposure, and endoscopic pharyngeal closure is not made. The endoscopic transcervical route circumvents the need for oropharyngeal dissection, and it offers a sterile operative field while enabling adequate exposure.²⁹ Spinal deformity, obesity, or ventral chest wall constraints, however, limit its application. It is also associated with a risk for airway swelling and dysphagia. An endoscopic transoral approach has also been proposed that obviates the need for resection through the hard palate while improving surgical access and endoscopic visualization.³¹ Although these evolving techniques may potentially improve patient outcomes, long-term studies with a direct comparison of outcomes are needed to better address the role of these emerging techniques.

Atlantoaxial osseous fusion requires immobilization for at least 3 months. We utilize custom brace/vest immobilization for 5 to 6 months when only a bony fusion is made. The rate of failure of fusion reaches 50% when immobilization is inadequate. Dorsal wire fixation should be avoided because skeletal growth will cause stress fatigue, with resultant wire fracture or disruption and possible injury to spinal cord.^{2,32,33} In the management of pediatric craniocervical fusions, the age of the patient, the occipitoatlantoaxial dimensions, and the ability to achieve screw purchase for an instrumented fusion must be taken into consideration. The senior author (A.H.M)

has used full-thickness rib to span the dorsal structures in children younger than 5 to 6 years of age; an attempt at instrumentation is made in children past that age.^{25,34} The treatment guidelines outlined above have yielded excellent surgical results, with no mortality or gross morbidity, in more than 1,700 children treated via anterior, lateral, or posterior surgical routes.

27.7 Specific Conditions Affecting Children

27.7.1 Grisel Syndrome

Grisel syndrome is defined as spontaneous atlantoaxial subluxation following parapharyngeal infection.^{2,11–13,15} This inflammatory subluxation is attributed to metastatic inflammation causing ligamentous stretching, subluxation, muscle spasm, and regional hyperemia with decalcification of ligamentous attachments. Thus, these children may present with torticollis, stiff neck with neck pain, or neurologic deficit. This may be after a case of tonsillitis, mastoiditis, retropharyngeal abscess, or otitis media or after a surgical procedure to correct one of these states. Children younger than 12 years of age are most commonly affected because of their relative ligamentous laxity and atlas vascularity.

Treatment involves CT and MR imaging. These identify the underlying abnormal anatomy and infection. It is critical that the source of infection be eliminated. Stabilization is achieved with a sterno-occipital mandibular immobilizing brace or a halo vest. In the acute phase, a Philadelphia collar may be applied to allow careful monitoring of respiratory function. Once the infection is under control, it is important that the

There is a ventral indentation into the inferior medulla by a bony mass proceeding from the inferior clivus. A hindbrain herniation is visualized. (b) MR imaging in T1 (left) and T2 (right) mode shows the ventral medullary and basilar artery compression. A hindbrain herniation and a cervicothoracic syrinx are visualized. (c) Three-dimensional computed tomography of the craniocervical junction viewed from within. A proatlantal segmentation defect is seen. A protrusion from the inferior clivus extends into the ventral foramen magnum. There is basilar invagination present and atlas assimilation laterally. (d) Postoperative MR imaging in T1 (left) and T2 (right) mode visualizing the posterior fossa and cervical spine. craniocervical dynamics be carefully assessed. In the author's own series of 52 children, a fusion procedure was required in 2 patients.² A delayed diagnosis of torticollis and ligamentous instability following an upper respiratory infection in infants often confounds effective treatment.

27.7.2 Assimilation of the Atlas and the Klippel-Feil Syndrome

Atlas assimilation is defined as segmentation failure between the fourth occipital and first spinal sclerotome. This occurs in

0.25% of the population; it may be unilateral, bilateral, segmental, or focal and in most instances occurs in conjunction with other abnormalities. Atlas assimilation was present in 380 of 3,300 patients with craniocervical abnormalities evaluated in an initial series of the senior author.²² A Chiari 1 malformation is typically present in more than one-third of such individuals.³⁵ Associated segmentation failure of the second and third cervical vertebrae leads to atlantoaxial instability that often progresses to a reducible basilar invagination (► Fig. 27.7a–d). This is more common in children younger than 14 years of age, after which irreducible basilar invagination occurs. During the phase of reducibility, prolific granulation tissue crowning the

The patient presented with weakness in the upper limbs and a diminished gag reflex with mirror hand movements. Note the segmentation failure at C2 and C3. (b) Frontal two-dimensional computed tomographic reconstruction of the craniocervical region identifies atlas assimilation and an abnormal position of the odontoid process in a 14-year-old. (c) This child had previously undergone magnetic resonance (MR) imaging for neck pain at 8 years of age. There is a mild atlantoaxial dislocation with probable atlas assimilation. However, the cervicomedullary junction is not compressed. (d) Composite of T2-weighted MR imaging in the midline (left) and paramedian (right) locations. The MR imaging at the age of 14 years now shows gross atlantoaxial dislocation with basilar invagination of the odontoid process into the foramen magnum, compressing the inferior medulla.

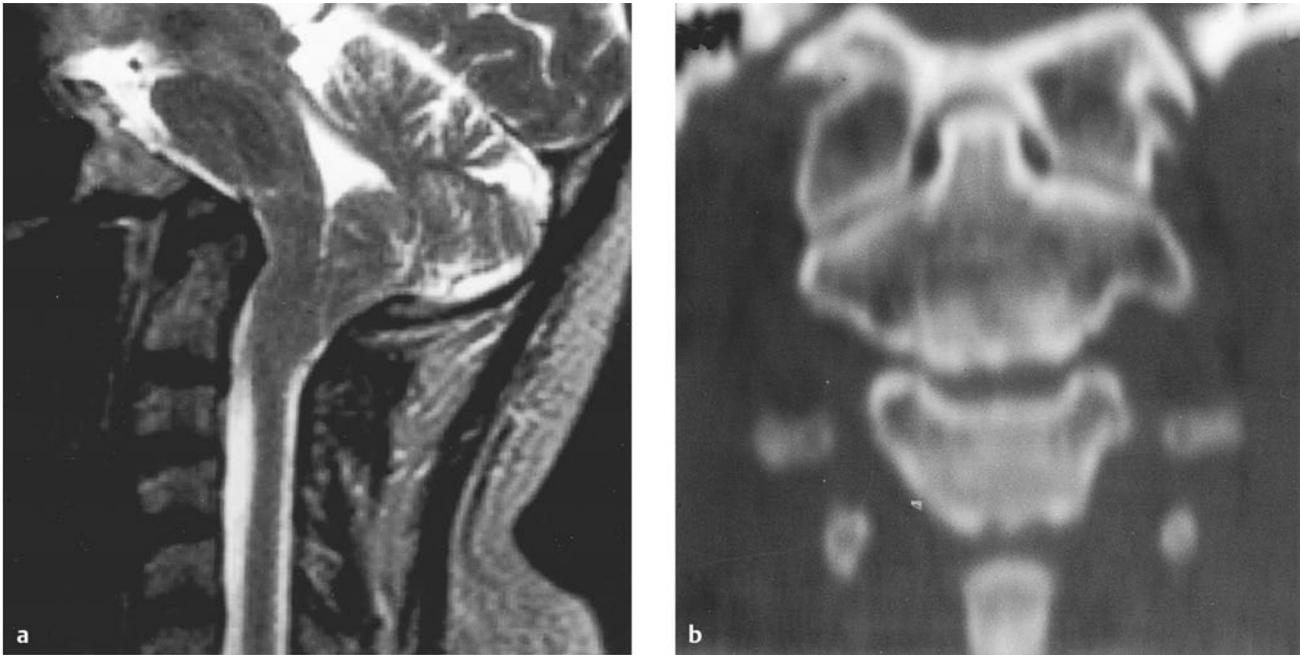

Fig. 27.8 (a) Midsagittal T2-weighted magnetic resonance imaging of the craniocervical region. This demonstrates a hypoplastic basiocciput, with the clivus nearly horizontal. There is atlas assimilation, with the anterior arch of the atlas located between the inferior clivus and the odontoid process. The vertical height of the posterior fossa is grossly reduced. The clivus-odontoid articulation indents into the mid medulla. Hindbrain herniation is visualized. (b) Coronal computed tomography through the plane of the odontoid process reveals atlas assimilation and abnormal craniocervical relationships.

odontoid process aggravates cervicomedullary compression. In irreducible basilar invagination, an associated horizontally oriented clivus and abnormal grooving occur behind the occipital condyles as a result of upward migration of the axis vertebra onto the assimilated atlas, leading to irreducibility (► Fig. 27.8a, b). Hence, atlantoaxial dislocation or basilar invagination is more likely to be reducible in children younger than 16 years. This is especially pertinent in the surgical management of hindbrain herniation syndromes because posterior decompression alone does not address the underlying craniocervical instability.

Acute trauma (e.g., flexion-extension injuries) and chronic trauma (e.g., from carrying loads on the head, as in developing countries) have been implicated in precipitating symptoms of atlantoaxial instability. This is more common when atlas assimilation is present in combination with segmentation failure of the second and third cervical vertebrae. Unilateral atlas assimilation may present as torticollis in a young child. It is essential that these anomalies be recognized during operative positioning involving excessive head rotation.

The classic triad of Klippel-Feil syndrome includes a short neck, a low posterior hairline, and limitation of cervical motion. This syndrome is commonly associated with atlas assimilation, fused vertebrae, segmentation anomalies, and spina bifida occulta. Scoliosis has been identified in 50% of reported cases.² Commonly associated congenital abnormalities include facial developmental anomalies (cleft face, deafness, high-arched palate, and facial palsies) and cardiovascular abnormalities (mitral valve disease, ventricular septal defects, aortic coarctation, and patent ductus arteriosus). Thoracic anomalies, including skeletal dysplasia, ectopic lung, and rib fusions, can occur in up to

20% of individuals. Genitourinary tract anomalies, including unilateral kidney, horseshoe kidney, and ectopic kidneys, occur in up to 30% of individuals. Hearing loss is generally of a mixed conductive and sensorineural type and may occur in 18% of children. It is imperative that these abnormalities be diagnosed and addressed perioperatively.¹

27.7.3 Atlantoaxial Rotatory Subluxation

The biomechanical properties of the pediatric craniovertebral junction, described earlier, predispose children to the development of atlantoaxial rotatory subluxation, which may also arise in conjunction with congenital (Down syndrome, Morquio syndrome) and acquired (trauma, preceding nasopharyngeal infections, Grisel syndrome) conditions.^{9,36,37} Symptoms commonly include cervical pain, limitation in cervical rotation, and torticollis that often leads to the characteristic “cock robin” position, in which rotation of the head and neck toward opposite sides is combined with cervical flexion (► Fig. 27.2d).^{37,38}

Upon presentation, the work-up includes a detailed clinical history with documentation of any preceding trauma, infectious or inflammatory conditions, and additional symptoms associated with an underlying congenital condition. An accurate determination of symptom onset is critical because this dictates whether a conservative or an operative management plan is appropriate. Clinical examination helps differentiate atlantoaxial rotatory subluxation from torticollis.³⁸ A thin-cut CT examination of the cervical spine with three-dimensional reconstruction helps identify the abnormal locked configuration of the

C1–C2 facet joints and also aids in preoperative planning (► Fig. 27.2a–d). A dynamic CT examination with the head in neutral and lateral rotation toward each side has also been recommended to document the limitation or loss of motion between the C1 and C2 levels during lateral rotation that is considered diagnostic. MR imaging is essential to evaluate ligamentous disruption, although in some chronic cases, radiographic changes may not be evident because of long-standing ligamentous laxity (► Fig. 27.2e,f).

Treatment entails cervical realignment with immobilization. In patients without a preceding infection, an initial trial of external bracing, with appropriate antibiotics and muscle relaxants, is undertaken. Otherwise, cervical traction (refer to earlier section on surgery) with the concurrent use of muscle relaxants, is needed to restore cervical anatomical alignment. For children with an acute presentation and a symptom duration of less than 2 weeks, an external cervical orthosis, with close clinical and radiographic follow-up, may suffice to maintain realignment and establish immobilization for healing.^{37,38} For those with a subacute presentation, symptom recurrence, or repeated subluxation, closed reduction with a cervical halter or halo traction is advocated, preferably in an inpatient setting.³⁸ If cervical alignment is reestablished, then an external orthosis should be continued for at least 3 months. For those with chronic or refractory symptoms or recurrent atlantoaxial rotatory subluxation, operative fixation with occipital-cervical arthrodesis is advocated because the ligamentous complex may be irreversibly damaged. Left untreated, atlantoaxial rotatory subluxation often leads to chronic pain, rotational deformity, and pharyngeal compression.³⁸ Moreover, a delayed diagnosis is often responsible for the failure of conservative treatment and increases the risk for recurrence.³⁷

27.7.4 Basilar Invagination

Basilar invagination implies ascent of the vertebral column through skull base.² It is a primary developmental defect and is usually associated with block vertebrae, fusion defects, and occipitalization of the atlas vertebra. If unilateral condylar hyperplasia occurs, this often leads to torticollis. The common manifestations of dysgenesis are the Chiari 1 malformation and syringohydromyelia, which occurs in 35% of patients. The terms *basilar invagination*, *basilar impression*, and *platybasia* require clarification. Basilar invagination implies the primary form, consisting of a distinct developmental defect of the chondrocranium. Basilar impression refers to the secondary, acquired form of invagination that is due to the bone softening that occurs in rickets, hyperparathyroidism, osteomalacia, Paget disease, Hurler syndrome, and other diseases, such as Hadju-Cheney syndrome.^{2,5} Platybasia refers only to an abnormally obtuse basilar angle formed by joining the plane of the clivus with the plane of the anterior fossa of the skull. This angle is of anthropologic significance only. There are no symptoms or signs that can be attributed to platybasia alone. It is not a measure of basilar invagination, although it may be associated with invagination.

Basilar invagination implies involvement of the basioccipital, exoccipital, and squamous occipital bone and is of two types. In anterior or ventral basilar invagination, the basiocciput is shortened and the clivus is small and may be horizontally oriented, leading to rostral displacement of the foramen magnum. This is

often associated with platybasia and hindbrain herniation syndromes. The paramedian type of basilar invagination involves hypoplasia of the occipital condyles with dorsal displacement of the clivus into the posterior fossa. The clivus invagination is compensated for by an excessive downward curving of the lateral portion of the squamous occipital bone.

Basilar invagination should be suspected when the lateral atlantoaxial articulation cannot be visualized on the open-mouth projection radiograph. A definitive radiographic diagnosis involves verifying the pathologic alteration in the relationships of affected bone and neural structures on radiographs and on CT and MR imaging studies (► Fig. 27.8a,b). In our series, neurologic deficit was usually present in patients older than 8 years of age if the effective sagittal diameter (subarachnoid) of the foramen magnum was less than 19 mm.

Cervical traction should be applied with an MR imaging-compatible crown halo. In the event of an associated Chiari malformation, ventral cervicomedullary bony decompression is performed in cases of irreducible invagination before the posterior surgical procedure. Failure to do so results in lack of neurologic improvement or progression of neurologic deficit. The ability to reduce the invagination is age-related, as previously described for atlas assimilation.²² If present, syringohydromyelia is effectively managed by proceeding with ventral decompression first. This enables restoration of the craniospinal cerebrospinal fluid (CSF) dynamics and resolution of the syringohydromyelia.³⁹ Any associated hydrocephalus should be treated by ventriculoperitoneal shunting. Endoscopic third ventriculostomy is not recommended, given the abnormal anatomy of the basiocciput and high-riding basilar artery.

27.7.5 Basilar Impression and Bone Softening Syndromes

Basilar impression, or secondary basilar invagination, arises secondary to congenital (osteogenesis imperfecta, spondyloepiphyseal dysplasia, acro-osteolysis, Hurler syndrome, achondroplasia) or acquired (Paget disease, osteomalacia, hyperparathyroidism, renal rickets) skeletal metabolic disorders.^{20,40,41} Anatomically, there is infolding of the squamous occipital bone, leading to elevation of the posterior fossa floor with invagination of the foramen magnum margin.²⁰ The basiocciput is also elevated and foreshortened, with associated truncation and relative horizontal orientation of the clivus that leads to an acute craniocervical angle. Anteroposteriorly, the petrous temporal bone is also deformed. These changes ultimately permit the clivus–atlas–odontoid complex to assume an abnormally rostral location within the foramen magnum, further restricting the posterior fossa volume.

The rostral extent of the invagination dictates the attendant neurologic manifestations (► Fig. 27.9a,b). The brainstem is elevated and splayed over the ventrally situated clivus–atlas–odontoid complex. In addition to causing mechanical compression, this acts as a fulcrum by which traction is applied to the caudal brainstem and rostral cervical spinal cord, producing bulbar dysfunction and myelopathy. The lower cranial nerves are stretched and distorted as the brainstem is forced upward, resulting in characteristic cranial nerve palsies. Cerebellar involvement may be primary, caused by compression from the

Fig. 27.9 (a) Lateral midsagittal magnetic resonance (MR) imaging (T1-weighted) of the head and upper cervical spine in a 7-year-old with basilar impression secondary to osteogenesis imperfecta. There is a horizontal clivus. The upper cervical spine is within the foramen magnum. This angulation causes a 90-degree indentation into the pontomedullary junction. There is secondary aqueductal stenosis with hydrocephalus. The vertical height of the posterior fossa is markedly reduced. Cerebellar tonsillar herniation is seen down to the C3 level. (b) Composite of T2-weighted axial MR imaging through the plane of the clivus (left) and 1 cm rostral to the dorsum sellae (right). There is upward invagination of the petrous bone and the atlas and axis seen on the left. The basilar artery is horizontal in its orientation at the level of the pontomesencephalic junction.

foramen magnum infolding, or secondary, caused by hindbrain herniation. Neurologic dysfunction may thus be coupled with hydrocephalus, syringohydromyelia, and hindbrain herniation. This acquired form of hindbrain herniation may lead to syringohydromyelia.

The pathogenesis of secondary invagination and osteochondroplasia remains obscure. The intrinsic bone fragility of the chondrocranium leads to deformation of both the skull base and cranial vault due to ineffective load bearing. Recurrent pathologic microfractures and chronic bone remodeling, evidenced by abnormal calluslike bony proliferation seen intraoperatively and also on radioactive imaging studies, may further contribute to bony deformation.²⁰

In pediatric patients with basilar impression or upper cervical abnormalities, the author has recommended a customized Minerva orthosis to “shore up” the skull and prevent the progression of secondary invagination.^{20,42} If a neurologic deficit has occurred secondary to ventral compression, a transoral or transmaxillary decompression, followed immediately by dorsal occipitocervical fixation with occipitocervical instrumentation and autologous bone grafting, must be undertaken. Postoperatively, occipitocervical immobilization must be continued through a modified shell custom-built brace until skeletal maturity is achieved. If any hydrocephalus due to secondary aqueductal stenosis is present, it must be treated first.

Surgical intervention was well tolerated in the author’s series, with a 100% fusion rate, effective neural decompression, and symptom improvement. However, although functional improvement persisted, basilar invagination progressed in 80% of the patients despite successful fusion.²⁰ In all these patients, the entire fusion mass migrated rostrally as a result of further squamous occipital and petrous bone infolding. Additionally, the posterior fusion mass tends to act as a fulcrum on which the

lever arm of the anterior skull base turns, thus exacerbating ventral compression. The author has found that a Minerva orthosis provides ventral cranial base stability and enables symptomatic relief by preventing further skeletal deformity. Until the fundamental molecular anomalies can be addressed, the author feels that all intervention in the primary or acquired developmental form of basilar impression must be considered palliative. In contrast, acquired forms have a better prognosis because the underlying metabolic or biochemical abnormalities can be corrected.

27.7.6 Down Syndrome

Down syndrome is the most common chromosomal disorder, with an incidence of 1 in 700 live births. Atlantoaxial instability is the most prevalent craniocervical abnormality, present in up to 24% of patients, although it is symptomatic in fewer than 1% of affected individuals.² The early diagnosis and surgical treatment of craniocervical instability avert development of the severe neurologic deficits often triggered by minor trauma. Os odontoideum is a frequent finding in craniocervical junction instability associated with Down syndrome (► Fig. 27.4b).

It is now recognized that more than 50% of cases of craniocervical instability involve the occiput-atlas junction. Thus, atlantoaxial fixation without occipital incorporation can lead to neurologic disaster. The author mandates occipitocervical fixation in the presence of cranial settling, reducible basilar invagination, unstable os odontoideum, and anterior, posterior, or lateral cranial displacement of the spine.^{20,21,33,43,44} Atlantoaxial fusion is indicated if craniocervical instability is limited to the C1–C2 articulation. This author recommends atlantoaxial fusion if dynamic cervical radiographs indicate a predental space of more than 6 to 7 mm.⁴³ In older children (older than 10 years),

Repeated aspiration pneumonia and failure to thrive with weak arms brought her to neurosurgical attention. There is dorsal foramen magnum compression of the cervicomedullary junction. Note the hydrocephalus and the vertical orientation of the brainstem. (b) Axial computed tomographic scan through the plane of the foramen magnum visualizes the constriction in the sagittal as well as the coronal diameter. transarticular screw fixation or atlas lateral mass screw–C2 pars screw with rod fixation can be performed safely.³⁴

27.7.7 Skeletal Dysplasias

These are divided into the following categories: (1) osteochondrodysplasia, (2) dysostosis, (3) chromosomal aberration, (4) idiopathic osteolysis, and (5) primary metabolic abnormal-

ities.^{5,24} These disorders include achondroplasia, spondyloepiphyseal dysplasia, multiple epiphyseal dysplasia, atrophic tonotropic dysplasia, Crouzon and Apert syndromes, neurofibromatosis, osteogenesis imperfecta, and a multicentric type such as the Hadju-Cheney form.^{19,24,40,41} In all, paramesial invagination (side to side) occurs together with a reduction in the sagittal diameter of the foramen magnum compounded by a dural shelf that forms through thickening and invagination

of the posterior dura into the cervicomedullary junction. This causes dorsal cervicomedullary compression in addition to the bony abnormality. Cervical stenosis may also be present in conditions such as achondroplasia and Morquio syndrome. Atlantoaxial instability occurs frequently in skeletal dysplasias. This is most common in children younger than 3 years of age and leads to cervicomedullary compromise, which typically manifests as sleep apnea and progressive spastic quadriparesis.²⁴ Definitive surgical treatment entails dorsal craniocervical decompression with duraplasty to address the cervicomedullary compression (► Fig. 27.10a-c). CSF shunting is required for hydrocephalus, which results from jugular bulb compression. The management of spondy-

loepiphyseal dysplasia is further complicated by a presentation in early infancy with associated atlantoaxial instability. Our approach has been to use a custom-built orthosis for external bracing until definitive surgical treatment can be performed by 3 to 4 years.

27.7.8 Segmentation Failures, Fusions, and Remnants at the Foramen Magnum and Atlas

In these developmental anomalies, bony projections from the clivus or lateral aspect of the foramen magnum cause central or

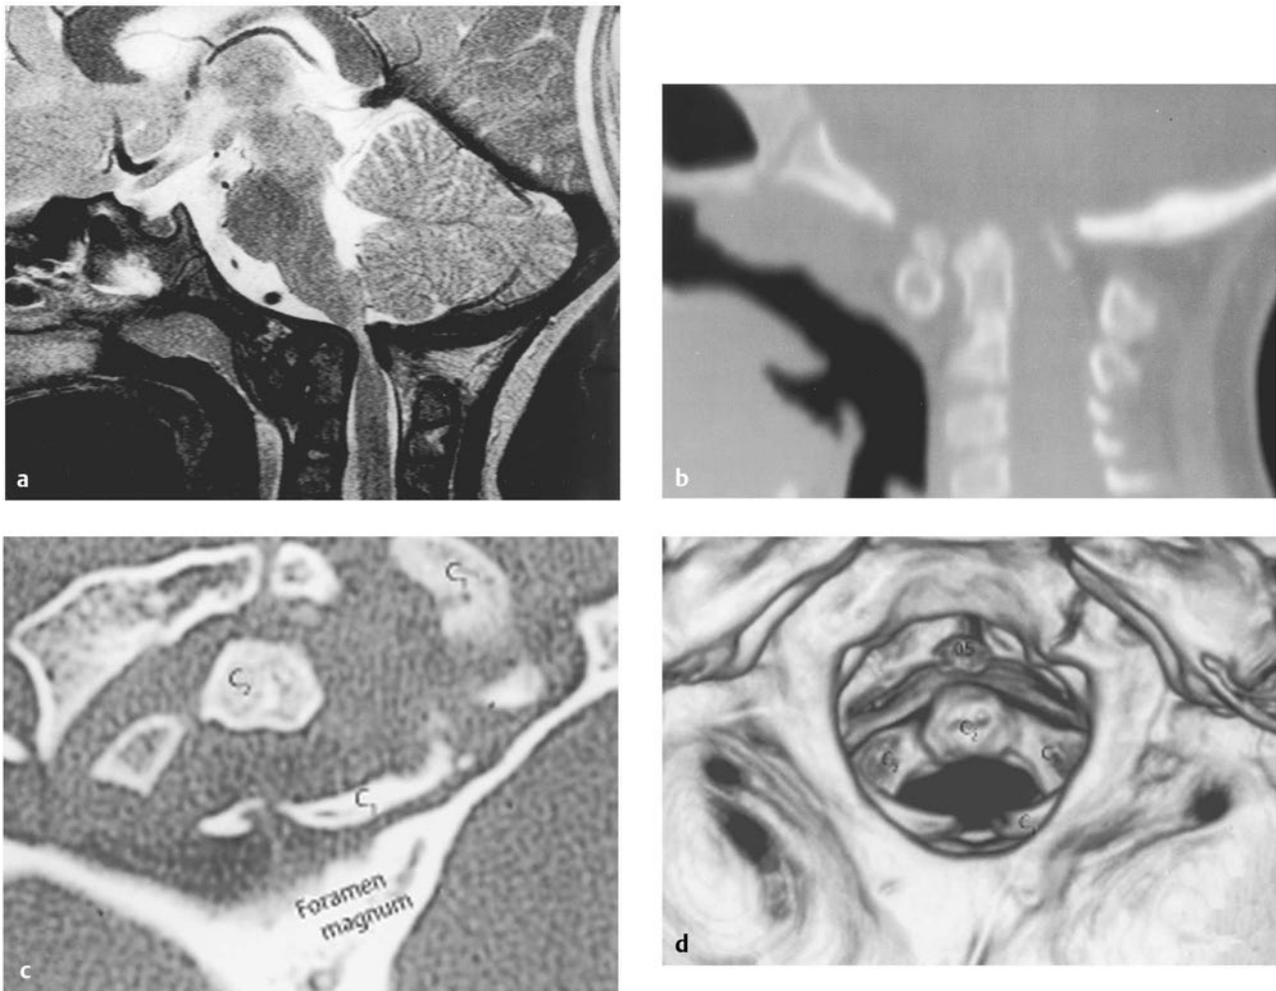

Fig. 27.11 (a) Midsagittal T2-weighted magnetic resonance imaging of the craniocervical junction. An hourglass constriction of the cervicomedullary junction is evident. The ventral component is the dorsal aspect of the axis body, and the dorsal component of the compression is the posterior arch of the atlas. A dystopic os odontoideum is evident. This patient presented with quadriparesis and lower brainstem dysfunction. (b) Midsagittal computed tomographic (CT) two-dimensional reconstruction of the craniocervical region. A dystopic os odontoideum resides above the anterior arch of the atlas between the inferior clivus and the ascended axis body. The posterior arch of the atlas has assumed a location just anterior to the posterior rim of the foramen magnum, causing severe compression of the cervicomedullary junction. (c) Axial CT through the plane of the foramen magnum. The anterior arch of the atlas is bifid, as is the posterior arch. The axis body is seen within the center of the spinal canal. (d) Three-dimensional CT scan of the craniocervical region viewed from within the foramen magnum. Note the bifid posterior arch of C1. Note also the separate os odontoideum and the C2 axis body in the center of the spinal canal.

paramesial invagination, respectively. High-resolution CT with three-dimensional reconstruction has facilitated greater recognition of the anomalies, which are most frequently seen in children between the ages of 2 and 16 years.⁴⁵

Atlas segmentation failures result in abnormal articulation between the clivus, atlas, and odontoid process. Other variations consist of unilateral or bilateral absence of the posterior arch of the atlas. An isolated bifid posterior arch of the atlas is commonly encountered and is not clinically significant. When it is associated with a bifid or bipartite anterior arch of the atlas, the two halves of the atlas vertebra act as a complex “Jefferson fracture.” The resultant lateral displacement leads to basilar invagination and caudal migration of the occipital condyles onto C2, causing neurovascular injury. Hence, bifid anterior and posterior arch of the atlas mandates surgical fixation beyond the age of 4 years. In the author’s experience, customized orthoses were used until the age of 3 to 4 years, after which occipitocervical fixation was undertaken if the pathologic anatomy persisted.

27.7.9 Odontoid Abnormalities

The most common odontoid abnormality is an os odontoideum. This term refers to an independent bone that is usually located in the position of the normal odontoid tip near the basiocciput and the area of foramen magnum, where it may ultimately fuse with the clivus. It is not an isolated dens but exists apart from a hypoplastic dens. Radiographically, an os odontoideum has smooth cortical borders and is separated by a variable gap from a small odontoid process. There is associated incompetence of the cruciate ligament and subsequent atlantoaxial instability (► Fig. 27.11a–d)

Os odontoideum is more common in association with ligamentous laxity and collagen disorders, as in Down syndrome and Morquio syndrome.^{15,46} Os terminale, on the other hand, represents failure of the secondary ossification center of the dens to fuse with the odontoid. It is not associated with mechanical instability because it lies above the transverse ligament. Os terminale is therefore not clinically significant.

There is now increasing evidence that os odontoideum is frequently associated with trauma at an early age.^{46–48} This may result in either an odontoid fracture or a stress injury at the neck of the odontoid process, leading to subsequent separation of the bone and the formation of a sequestrum. In the author’s series, a fully developed odontoid process was seen in a significant number of children before an injury that occurred between the ages of 1 and 4 years. An os odontoideum subsequently developed in these same children.²

The movement of an os odontoideum is individual in each child and hence must be carefully studied before treatment is undertaken. It is not uncommon for an os odontoideum to be recognized in a child following minor trauma when lateral cervical spine radiographs are taken. If there are abnormal excursions of the craniocervical junction, ligamentous laxity has already taken place, and this author mandates that surgical fixation should be undertaken.

Pearls

In this authors’ experience:

- It is not uncommon for children with craniocervical abnormalities to present with basilar migraine, dysphagia, sleep apnea, the syndrome akin to central cervical spinal cord dysfunction, and scoliosis.
- Torticollis in children may represent craniocervical abnormalities. Three-dimensional CT is required.
- When unexplained neurologic symptoms and signs are associated with craniocervical abnormalities, vertebral angiography should be performed with dynamic motion studies.
- Crown halo application in children requires the placement of six to eight pins beneath the cranial equator. Finger tightening of the pins is used before 2 years of age. At 5 years of age, 4 lb of torque pin pressure is used. The “adult” 8-lb torque is applied in children past 12 years of age.

28 Congenital Intraspinal Cysts

Andrew B. Foy and Bruce A. Kaufman

Congenital cystic lesions of the spine are rare entities in children. These developmental lesions are often slow-growing and can present in childhood or early adulthood with a range of symptoms related to nerve root or spinal cord compression. The lesions are readily identified on magnetic resonance (MR) imaging. Although they are often identified as isolated lesions, many congenital cysts are associated with various forms of spinal dysraphism and vertebral column abnormalities.

Arachnoid cysts are benign arachnoid diverticula filled with spinal fluid that can occur along the entire neuraxis. Spinal arachnoid cysts occur less frequently than intracranial arachnoid cysts. Little has been reported on the incidence of spinal arachnoid cysts in the general population. A review of children undergoing routine MR imaging of the brain found that intracranial arachnoid cysts were present in 2.6% of the children, but it is presumed that spinal arachnoid cysts occur much less frequently.¹ In a retrospective review, 25% of arachnoid cysts that required surgical intervention were intraspinal.²

Neurenteric cysts are endodermal inclusion cysts of the spinal canal. Numerous names have been given to this entity in the literature, and all of them describe cystic structures of endodermal origin. Frequently used names in the literature include *neurenteric cyst*, *archenteric cyst*, *intestionoma*, *enterogenous cyst*, *dorsal enteric fistula*, and *neurenteric canal remnant*.³ For the purposes of this chapter, the term *neurenteric cyst* will be used.

Spinal dermoid and epidermoid cysts are congenital tumors thought to arise from abnormal rests of ectodermal cells. These lesions can occur in the intraspinal or intracranial space. In a large series published by Lunardi et al, spinal dermoid and epidermoid tumors represented 2.2% of all surgically resected primary spinal tumors.⁴ The lesions commonly present in early childhood and account for 17% of all primary spinal tumors diagnosed within the first year of life.⁴ Dermoid tumors are more common in the spine, whereas epidermoid tumors are more commonly cranial in location.

28.1 Arachnoid Cysts

Although intracranial arachnoid cysts are more prevalent in males, a similar distribution has not been found for spinal arachnoid cysts. Spinal arachnoid cysts have on rare occasion been found to be familial.⁵⁻⁷ These lesions have also been reported to be associated with genetic conditions, including hereditary distichiasis, neurocutaneous melanosis,⁸ and Noonan syndrome.⁹ Spinal arachnoid cysts are also prevalent in patients with spinal dysraphism, most frequently presenting in those with open neural tube defects or split-cord malformations.¹⁰

Arachnoid cysts have been reported in the extradural and intradural space. Rare cases of intramedullary arachnoid cysts have also been reported.^{11,12} The majority of these cysts are solitary and located within the thoracic spine, although cases of multiple spinal arachnoid cysts have been reported.¹³ Arachnoid cysts, unlike neurenteric cysts, are more likely to be located dorsal to the spinal cord.

The mechanism that leads to the development of a spinal arachnoid cyst is not entirely known. There are likely multiple causes for these lesions. Intradural arachnoid cysts have been postulated to arise from congenital diverticula of the arachnoid. Extradural arachnoid cysts are thought to arise from the herniation of arachnoid through a weakness in the spinal dura.¹⁴ Perret et al suggested that spinal arachnoid cysts are derived from an expansion of the septum posticum, an arachnoid partition dividing the posterior spinal subarachnoid space.¹⁵ This theory is supported by the frequent reports of congenital intradural and extradural arachnoid cysts found dorsal to the spinal cord.

Some spinal arachnoid cysts likely arise secondary to inflammation, trauma, or subarachnoid scarring.¹⁶⁻¹⁸ Spinal arachnoid cysts in children with myelomeningocele have been postulated to result from extensive subarachnoid scarring and alterations in the flow of spinal fluid, and they may be acquired lesions.¹⁰

A number of theories have been proposed to account for the growth and progression of spinal arachnoid cysts. The most common theory states that a ball valve mechanism exists between the cyst and subarachnoid space, allowing the one-way flow of spinal fluid into the arachnoid cyst.^{19,20} Other investigators have postulated that an osmotic gradient exists between the cyst and extracystic space, or that there is fluid hypersecretion by the cells lining the cyst wall.²¹

The symptoms related to spinal arachnoid cysts can be nonspecific and subtle. Symptoms are usually the result of compression on the spinal cord or spinal nerve roots. About 50% of children with arachnoid cysts present with pain.^{22,23} Children often report back pain or radicular arm, thoracic, or leg pain. Other common symptoms include motor weakness, gait instability, sensory disturbances, and urinary incontinence or retention. Symptoms are often aggravated by upright positioning, coughing, and straining as fluid is forced into the arachnoid cyst or intraspinal pressures fluctuate. Children may also present with unexplained scoliosis or kyphosis.²⁴ Physical examination often reveals evidence of a myelopathy or radiculopathy, depending on the location and level of the lesion. Children may also have point tenderness of the midline spine or palpable evidence of scoliosis.

Plain radiographs of the spine may be entirely normal or show subtle evidence of an arachnoid cyst. The presence of kyphoscoliosis may be apparent on radiographs. There may be nonspecific findings of an underlying mass, including scalloping of the vertebral body, thinning of the pedicles, and widening of the interpedicular distance. Computed tomography (CT) after myelography can show evidence of cord compression and the flow of contrast around or into an arachnoid cyst, but this study has largely been supplanted by MR imaging as the diagnostic test of choice.²⁵

MR imaging reveals a cystic structure with fluid that is isointense to spinal fluid on T1- and T2-weighted images^{25,26} (► Fig. 28.1). Occasionally, increased protein in the cyst will cause a T1-weighted signal slightly higher than that of (► Fig. 28.1c). MR imaging has the ability to identify both the lesion and the degree of spinal cord and nerve root compression. The cyst wall usually is smooth and shows no evidence of

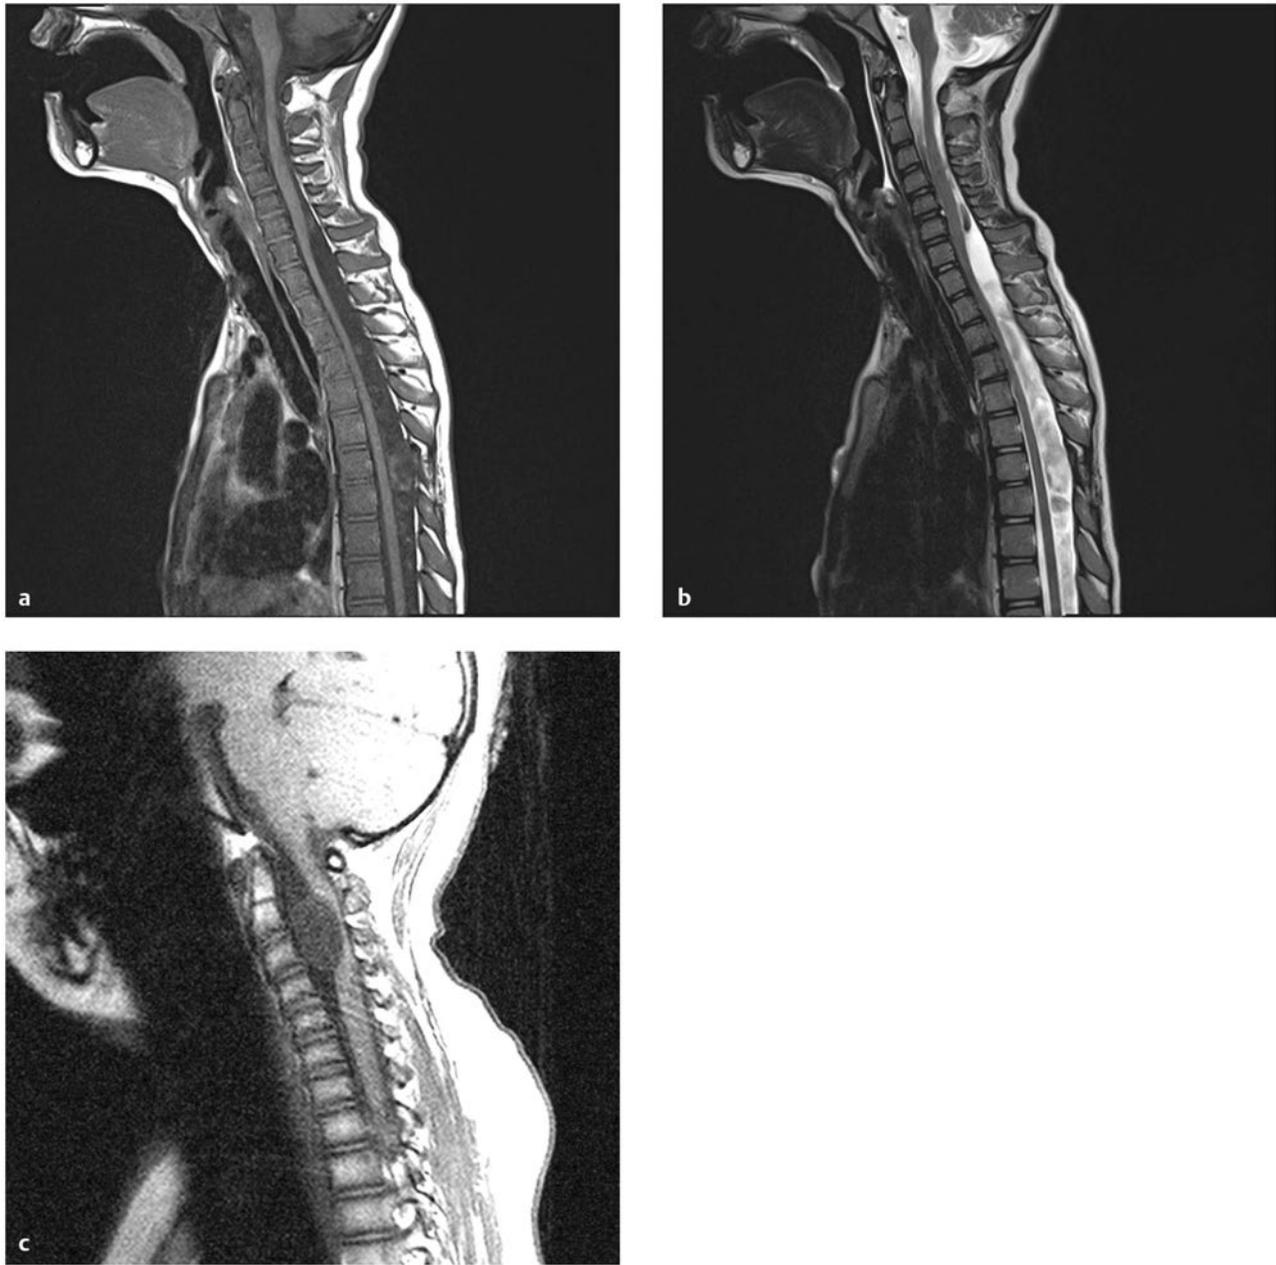

Fig. 28.1 Arachnoid cyst. (a) Arachnoid cysts are typically located dorsal to the cord, like this cervicothoracic lesion, with the cyst fluid slightly hypointense to cerebrospinal fluid (CSF) on T1-weighted sequences. Mild cord compression is seen. (b) On the T2-weighted sequence, the cyst fluid is hyperintense to CSF, and flow voids can be seen above and below the cyst, helping to define its extent. (c) The surgically proven arachnoid cyst shown is unusual in its location, anterior to the cord, and in its signal characteristics, which are slightly hyperintense to those of CSF. The flow void artifact (bottom of cyst) helps to define the lower cyst margin.

abnormal contrast enhancement. More recently, cine MR imaging has been used to show abnormal spinal fluid flow at the cyst wall boundary and dynamic cord compression.²⁷

Pathologically, these lesions are composed of a collagenous membrane lined by a flattened meningotheial cell layer. Focal areas of meningotheial cells may be present. Immunohistochemical labeling studies are often unremarkable.²⁸

The treatment of arachnoid cysts can range from simple observation to surgical fenestration or resection, although surgical

fenestration or excision of these lesions has been the treatment of choice for many years. Observation may be chosen for those cysts that are discovered incidentally in children without symptoms referable to the cyst.

When surgical treatment is chosen, a posterior approach is usually preferred because the majority of these cysts are dorsal to the spinal cord. Laminoplasty is often performed rather than laminectomy in an attempt to reduce the incidence of postoperative spinal deformity.²⁹ Intraoperative neurophysiologic

monitoring, including somatosensory evoked potentials and motor evoked potentials to monitor the function of the spinal cord during cyst excision, can also be employed.

For extradural arachnoid cysts, the cyst wall should be present immediately after the laminotomy has been performed. The cyst wall is dissected free of the surrounding tissues, and in most instances a small rent will be visualized along the dorsal surface of the dura. The cyst wall is completely resected, and the dura is closed with sutures. Intradural exploration can be performed if there is concern for intradural extension of the cyst. Rare instances of extradural arachnoid cysts without a clear intradural connection have been reported.³⁰

For intradural arachnoid cysts, the dura is opened and tacked back to expose the cyst. The cyst is carefully removed from the dural surface, spinal cord, and nerve roots under magnified vision (i.e., an operating microscope). When the cyst wall is densely adherent to the spinal cord or nerve roots, those parts of the wall are left behind. For ventral cysts, wide fenestration of the cyst into the subarachnoid space is often performed because it is difficult to access the entire cyst without putting significant traction on the spinal cord.³¹

Cyst-to-subarachnoid space shunting or cyst-to-pleura shunting is a viable surgical alternative.¹⁰ More recently, investigators have utilized intrathecal endoscopy to minimize the incision and bone removal; however, the utility of this approach is unclear.^{32,33} Percutaneous image-guided aspiration of spinal arachnoid cysts has been reported.^{34,35}

Outcomes of surgical treatment are good. Bond et al recently reported that 87% of patients had symptomatic improvement after surgical fenestration or resection of a spinal arachnoid cyst.¹¹ The recurrence rate of arachnoid cysts treated with excision or wide fenestration is low.^{11,31} Although short- and intermediate-term results have been good, some studies have suggested late worsening following the treatment of spinal arachnoid cysts.³⁶

28.2 Neurenteric Cysts

Neurenteric cysts are distinctly uncommon, accounting for roughly 1% of spinal neoplasms.^{37,38} Older retrospective studies have shown a slight male predominance.^{38,39} However, more recent studies have shown widely varying distributions.^{37,40–42} Patients can present with symptoms at any time during childhood or early adulthood.

The majority of spinal neurenteric cysts are located in the intradural extramedullary space ventral to the cervical or thoracic spinal cord. This is likely due to their origin from the foregut. Fewer than 5% of reported cases are wholly or partially intramedullary.⁴³ A distinct minority of these lesions have been identified in the lumbar region.⁴⁴

Although neurenteric cysts can occur in isolation, it is not uncommon for them to occur with other congenital spinal abnormalities. Neurenteric cysts have been found in association with various vertebral column anomalies, including partial sacral agenesis, block vertebrae, hemivertebrae, Klippel-Feil anomaly, and butterfly vertebrae.^{37,40,45} In addition, syringomyelia, split-cord malformations, spinal cord lipomas, and dermal sinus tracts have been found in association with neurenteric cysts.^{37,45,46} Although they are generally benign

in nature, dissemination and malignant transformation of these lesions have been reported.^{47,48}

The embryologic origin and pathogenesis of spinal neurenteric cysts are not entirely clear. Incomplete separation of the foregut from the notochord during early embryonic development seems to be an integral component in the development of a neurenteric cyst. During the third week of embryonic development, the mesoderm along the midline of the embryo coalesces to form the notochord. Also during the third week, intercalation of the notochord into the endoderm occurs briefly, and a primitive neurenteric canal forms connecting the endoderm and ectoderm through the notochord.⁴⁹ Neurenteric cysts likely are derived from abnormalities occurring during this early developmental period. Macdonald et al reviewed four theories of neurenteric cyst pathogenesis.⁴⁹ These theories include splitting of the notochord with an aberrant persistent connection between endoderm and ectoderm, incomplete or abnormal ex-calcation of the notochord, ectopic spinal rests of endoderm, and persistence of the primitive neurenteric canal.

A range of symptoms have been associated with spinal neurenteric cysts. Many present with the same constellation of symptoms seen in children with arachnoid cysts, including back pain, radicular pain, paresthesias, weakness, gait changes, and changes in bowel or bladder function. These symptoms generally result from compression on the neural and vertebral elements. Uncommon presentations of neurenteric cysts include unexplained fever,⁴⁰ cyst rupture with resultant chemical meningitis and arachnoiditis,⁵⁰ recurrent bacterial meningitis,⁵¹ and intracystic hemorrhage.⁵²

Plain radiographic images are of limited utility in the diagnosis of a neurenteric cyst. However, these studies can be useful in documenting the range of vertebral anomalies that are commonly found in conjunction with these lesions. Holmes et al noted that 77% of children with neurenteric cysts had abnormal plain radiographs.³⁹

MR imaging is the diagnostic test of choice (► Fig. 28.2). The signal characteristics of the cyst fluid are variable and depend largely on the protein content of the cyst fluid.⁵³ In general, the cyst fluid is isointense to slightly hyperintense compared with spinal fluid on T1- and T2-weighted imaging sequences. The cyst itself is often thin-walled and shows no evidence of enhancement. The degree of nerve root and spinal cord compression can also be ascertained from MR imaging.

Grossly, these lesions may be thin-walled or thick-walled. The cyst fluid can vary from clear to quite turbid. Light microscopy shows evidence of an epithelial layer, with goblet cells, ciliated cells, and squamous cells lying on a basement membrane. Immunocytochemical studies show cytokeratin and epithelial membrane antigen positivity in the endothelial cells.⁴⁹ Although the epithelium is presumed to be of gastric origin, Morita et al, using electron microscopy, found that the features of the epithelium of the wall of a recurrent neurenteric cyst were more consistent with a respiratory origin.⁵⁴

As for arachnoid cysts, surgical resection is the primary treatment modality for symptomatic neurenteric cysts. However, these lesions are often ventral in location, making surgical access difficult. Total excision of the cyst with decompression of the spinal cord and nerve roots is the goal of surgery. Subtotal resection is often necessary to avoid damage to the spinal cord and nerve roots when the cyst is highly adherent to these

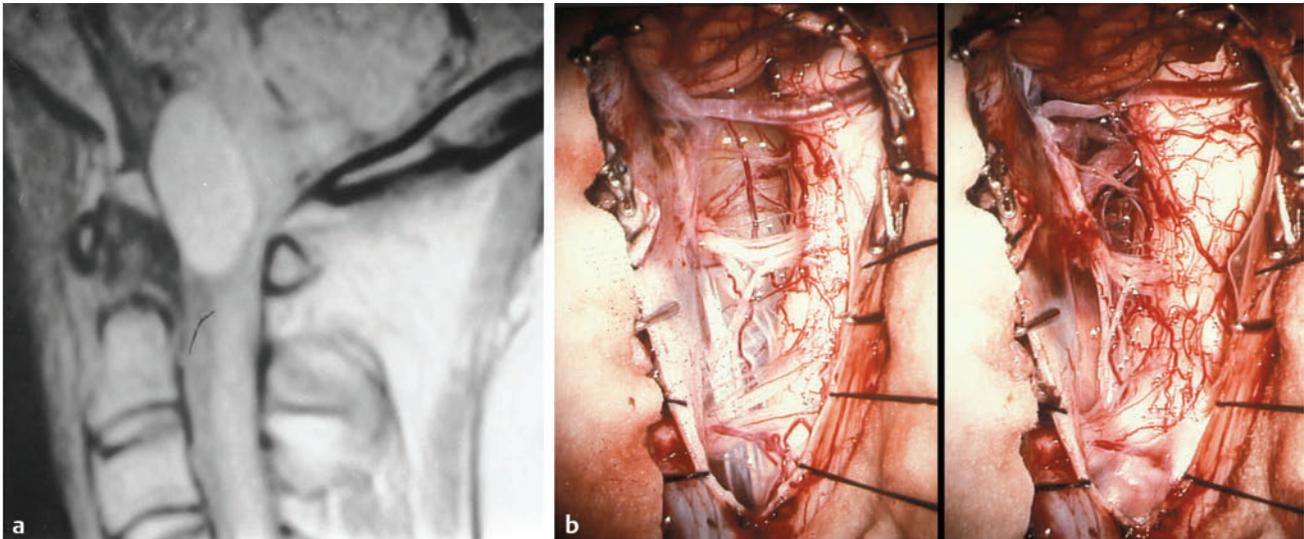

Fig. 28.2 Neurenteric cyst. (a) The neurenteric cyst in this sagittal T1-weighted magnetic resonance image is typical in location (anterior to the cord) and signal characteristics (slightly hyperintense). (b) Intraoperative view of the anteriorly placed, well-defined neurenteric cyst, surrounded by the vessels and nerves of the upper cervical spine, before and after complete resection. structures or when significant manipulation on the cord would be required to fully access an anterior lesion.

Both posterior and anterior approaches to these lesions have been reported. The posterior approach avoids the extensive bone work and fusion that may be required for anterior approaches, but ventrally located cysts are difficult to access or completely resect from a posterior approach. When ventrally located cysts are approached from a posterior laminoplasty, care must be taken to avoid undue traction on the spinal cord and nerve roots.^{37,40} The dentate ligaments can be sectioned to allow improved access to the ventral cord. Anterior approaches are technically more challenging, require more bone removal, and are likely to destabilize the spine, necessitating a fusion procedure. However, anterior approaches to ventrally located cysts offer more direct visualization and usually allow greater resection of the cyst wall.^{50,55,56}

Outcomes after the surgical resection of neurenteric cysts have been generally good. The majority of patients clinically improve following surgical intervention.^{37,40} More difficult to assess are the long-term outcomes and incidence of cyst recurrence. Recurrence of neurenteric cysts, especially incompletely resected lesions, has been reported. Chavda et al reported a 37% long-term recurrence rate in eight patients over a 30-year period.⁵⁷ The lesions were slow to regrow, with recurrences noted 4 to 14 years after the initial surgery. Other authors have found recurrence to be relatively uncommon.^{39,58}

28.3 Dermoid and Epidermoid Cysts

Dermoid and epidermoid tumors of the spine are found most commonly in the lumbar region and are usually intradural and extramedullary. In a series of 62 tumors in the region of the

conus medullaris and cauda equina, dermoid and epidermoid tumors represented nearly one-third of the total.⁵⁹ There are conflicting reports in the literature with regard to the male and female distribution of these lesions; however, the most recent series has shown equivalent rates among males and females.⁶⁰

Classically, spinal dermoid and epidermoid cysts have been thought to arise from an abnormal inclusion of ectodermal cell rests during closure of the neural tube between the third and the fifth week of gestation. Although there is little scientific evidence, some believe that the timing of the abnormal implantation of ectodermal cells determines whether a dermoid or an epidermoid tumor develops. The implantation of less differentiated ectodermal cells early in fetal life leads to the development of dermoid tumors, whereas the later implantation of ectodermal cells leads to more differentiated epidermoid tumors.^{60,61}

These spinal lesions can be iatrogenic. There is good evidence that the introduction of cutaneous cells during procedures such as lumbar puncture can lead to the development of dermoid tumors.⁶² The delayed development of dermoid tumors has also been reported in children with myelomeningocele.^{63,64} Although the dermoid tumors may be due to the inclusion of dermal elements during closure of a myelomeningocele, ventral dermoid tumors remote from the site of myelomeningocele closure in these children are likely the result of congenital rests of ectoderm cells.

Inclusion cysts of the spine are most commonly located in the lumbar region and are generally dorsal intradural and extramedullary lesions. Partially intramedullary or completely intramedullary dermoid tumors have been reported.^{60,65,66} Many congenital spinal and vertebral anomalies have been reported in association with spinal dermoids and epidermoids. Myelomeningocele, split-cord malformation, syringomyelia, and vertebral column fusion anomalies have been reported with

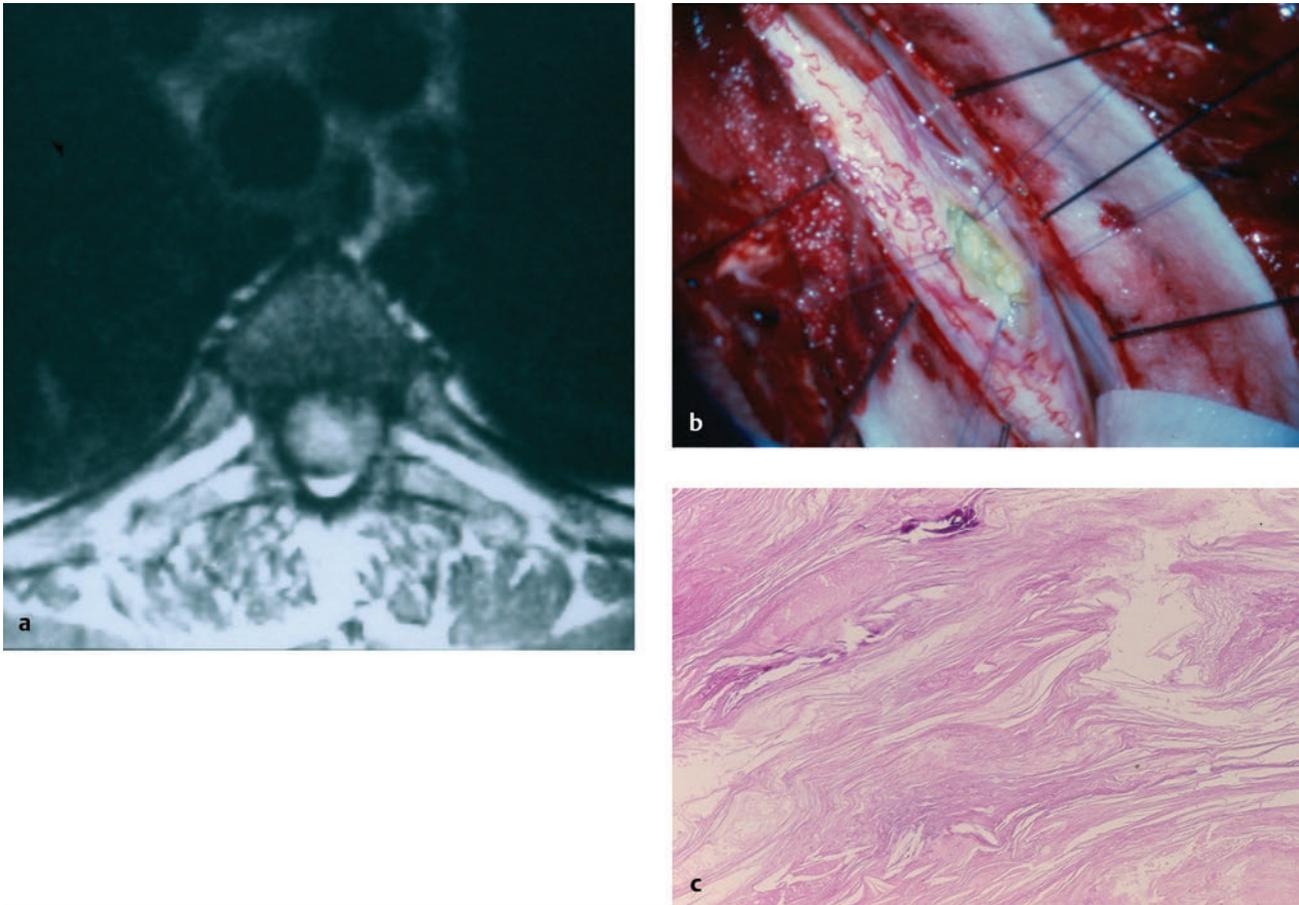

Fig. 28.3 Epidermoid cyst. (a) This epidermoid cyst is hyperintense on axial T2-weighted imaging. (b) Intraoperatively, the lesion was found to be intramedullary, located along the posterior-lateral aspect of the spinal cord (pia retracted with Prolene suture). (c) The membrane showed typical stratified, keratinized squamous epithelium.

intraspinal inclusion tumors. Dermal sinus tracts are particularly common in children with spinal dermoids.^{60,67}

Children harboring intraspinal dermoid or epidermoid tumors can have a range of symptoms. Many children present with symptoms that mimic the typical manifestations of spinal arachnoid or neurenteric cysts, including back and radicular pain, weakness, sensory disturbance, and bladder dysfunction. Scoliosis and kyphosis can occur in these patients. In patients with an associated dermal sinus tract, the presenting symptoms may be a consequence of local infection of the dermal sinus, frank meningitis, or spinal empyema.⁶⁸

Although a detailed neurologic examination is warranted to look for evidence of a myelopathy or radiculopathy, examination of the back is also important. Common cutaneous findings on examination of the spine include dimples above the gluteal cleft, dermal sinus tracts, hairy patches, and hemangiomas.

As for other types of spinal cysts, MR imaging is the test of choice for delineating these lesions. Epidermoid tumors tend to have signal characteristics similar to those of spinal fluid, with T1-weighted hypointensity and T2-weighted hyperintensity (► Fig. 28.3). Conversely, dermoid tumors often are hyperintense on T1-weighted images and have low signal intensity on

T2-weighted images. However, it should be noted that the imaging of dermoid and epidermoid tumors is highly variable.^{69,70} Diffusion-weighted imaging sequences have shown some early success in distinguishing dermoid and epidermoid cysts from other spinal lesions. Diffusion-weighted imaging sequences often show restricted diffusion in dermoid and epidermoid tumors, whereas arachnoid cysts have no such diffusion restriction.⁷¹

On gross examination, dermoid and epidermoid tumors are whitish yellow in appearance. The tumor capsule is filled with a soft white tissue composed of keratinized debris. Dermoids also have evidence of adnexal structures, including hair and hair follicles, and occasionally have calcium deposits. Epidermoid cysts on microscopic examination are composed of a layer of stratified squamous epithelium (► Fig. 28.3c). Dermoid cysts have a similar stratified squamous epithelium with interspersed sebaceous glands and hair follicles.

Surgery is the primary means of treating symptomatic spinal dermoid and epidermoid tumors. As the majority of these lesions are dorsal to the spinal cord and cauda equina, a posterior approach is usually indicated (► Fig. 28.3b). The goal of surgery is complete removal of the cyst and decompression of the spinal cord and nerve roots. The epithelial lining of these lesions is

often highly adherent to the spinal cord and nerve roots. Care must be taken to achieve as complete a resection as possible without damaging the neural tissues. Most case series have reported only a 40 to 50% rate of visual gross total resection at the time of surgery.^{4,72}

Surgical resection is often successful in stabilizing or improving preoperative symptoms. In recent series, 80 to 90% of patients stabilized or improving following surgical intervention.^{60, 72} Aseptic or cholesterol meningitis is a frequent postoperative complication. Some authors have advocated multiple lumbar punctures to treat postoperative aseptic meningitis.⁴ Long-term tumor control is good even when an incomplete resection is achieved. These lesions are slow-growing, and frequently, recurrence is seen many years after the initial resection.^{4,60,72}

Pearls

- Congenital intraspinal cysts are rare lesions that often present with subtle symptoms, including unexplained back or extremity pain.
- MR imaging is the diagnostic test of choice for detecting congenital intraspinal cysts.
- Complete resection of the cyst is frequently the treatment of choice, although complete resection may not be safe if there is significant adherence of the cyst to the surrounding neural structures.
- Cyst recurrence is fairly uncommon, but close observation is warranted following surgical treatment for any congenital intraspinal cyst.

29 Congenital Vertebral Anomalies

Douglas Brockmeyer

Congenital vertebral anomalies are relatively common disorders, ranging from simple, asymptomatic “block” vertebrae to complex combinations of anomalies involving multiple vertebral levels. They can occur anywhere from the craniovertebral junction to the coccyx. This chapter covers congenital vertebral anomalies from the cervical spine to the sacrum. Congenital vertebral anomalies may be associated with other birth defects, and awareness of these associations is important. To manage patients with congenital vertebral anomalies effectively, a firm grasp of the relevant embryology, classification, natural history, clinical evaluation, and treatment principles is essential.

29.1 Historical Background

Although spinal deformities have been recognized in the medical literature for centuries, it was not until the early part of the 20th century that the first vertebral anomaly syndromes were characterized. In 1912, Klippel and Feil reported a patient with the triad of low posterior hairline, short neck, and reduction in cervical spine motion, thus providing the first description of the syndrome that now bears their names.¹ A little over a decade later, Foix and Hillemand provided a classification scheme for caudal agenesis based on the extent of sacral and coccygeal involvement.² Significant advancements in the description and understanding of vertebral anomalies occurred with the development of spinal radiographs in the middle of the century, and extensive effort over the past 20 years by many authors, notably Winter et al,^{3,4} McMaster and Ohtsuka,⁵ and Pang et al.^{6–9} has provided tremendous insight into the pathogenesis, treatment, and prognosis of these disorders.

29.2 Embryogenesis

The sequential stages of the development of the spine have been extensively discussed in prior texts⁷ and will be only briefly reviewed here. The first six embryonic weeks set the stage for early vertebral development in a process known as primary neurulation. In that period, also known as the mesenchymal stage, the notochord develops in the first few embryonic weeks from cells within the Hensen node.¹⁰ Somitic mesodermal cells migrate from a position just caudal to the Hensen node and ultimately lie just lateral to the midline notochord. These cells coalesce into paired somites in a rostral to caudal direction, all under the influence of the notochord, the neural tube, homeobox genes, and cell adhesion proteins.^{11–13} The somites ultimately divide into sclerotomes and dermomyotomes, with each of the bilaterally paired sclerotomes giving rise to a single vertebral body and single set of posterior elements during a migrational phase in the fourth and fifth embryonic weeks.^{12–14}

Although this process of primary neurulation accounts for the formation of the vertebral column and spinal cord down to the lumbosacral junction, most sacral and coccygeal vertebrae develop from the caudal eminence in a poorly understood process called secondary neurulation.¹⁰ The caudal eminence is a

mass of undifferentiated cells at the caudal end of the primary neural tube.⁶ Secondary neurulation begins at approximately the fourth embryonic week and is responsible for the formation of the spinal cord, nerve roots, and vertebral column of the sacral and coccygeal areas.^{15,16} New insights into the complex manifestations of secondary neurulation are provided by Pang et al.^{8,9}

During the sixth embryonic week, the chondrification stage begins with the formation of three paired chondrification centers within a vertebra. One set of chondrification centers develops anteriorly to form the vertebral body, and two sets develop posteriorly to form the posterior elements. This process develops in a cranial and caudal direction from the cervicothoracic junction and is responsible for rapid vertebral column growth.¹⁷ It culminates at approximately the ninth embryonic week. Ossification of the cartilaginous elements begins shortly thereafter and ultimately ends somewhere between the 14th and 18th years of life.^{18,19} The intervertebral disk develops from tissue derived from perinotochordal mesenchymal cells and begins its formation in the chondrification stage.¹²

29.3 Epidemiology

Accurate statistics regarding congenital vertebral anomalies are difficult to come by because many patients are asymptomatic and the anomalies remain undiscovered. Incidence rates are also difficult to gather because many cases are discovered incidentally and never evaluated further. Furthermore, estimates are difficult to obtain in young children because of radiographic variations. At an early age, vertebrae have partially ossified centra and arches that may be confused with congenital vertebral anomalies.^{18,20}

An estimated 5% of fetuses have vertebral anomalies.²¹ About 3% of the normal population have one or two more than the usual 7 cervical, 12 thoracic, 5 lumbar, and 5 sacral vertebrae; approximately 2% of the population have one less.¹⁸ About 7 in 1,000 individuals in the general population have a congenital union of two or more cervical vertebrae.^{22,23} The incidence of caudal agenesis in Sweden was reported as 1 in 7,500 births, a number similar in magnitude to the 1 in 4,000 incidence found in Chicago.²⁴ The incidence of scoliosis of more than 10 degrees was reported as a little over 1% for students in Beijing,²⁵ but a slightly higher figure of 2 to 3% has been cited for idiopathic scoliosis in skeletally immature children in the United States.²⁶

29.4 Etiology

Congenital vertebral anomalies commonly result from abnormal development during the first trimester of pregnancy.²⁷ The nature and timing of the insult to the embryonic vertebral column determine the type of congenital abnormality that is produced. Hemivertebrae and hypoplastic vertebrae arise during the mesenchymal stage, with a disruption of the primary chondrification centers and a pairing defect of the responsible sclerotomes, respectively.¹⁷ Some authors have proposed that

vertebral body hypoplasia and aplasia, both common causes of kyphotic abnormalities, arise during the chondrification stage, possibly as a consequence of absent centrum vascularization.^{17, 19,28} Environmental factors, including infections such as tuberculosis, can also result in hypoplastic vertebrae and congenital scoliosis.²⁷

The etiology of osseous malformations in the cervical spine is probably multifactorial.²⁹ Autosomal-dominant inheritance of cervical ribs has been reported,³⁰ and the congenital cervical fusions occurring with abnormalities such as the Apert and Crouzon syndromes are probably based on autosomal-recessive and autosomal-dominant inheritance patterns, respectively.³¹ Genetic inheritance does not account for many of these lesions, however, and there is some evidence to suggest that congenital vertebral anomalies result from vascular occlusions during development.

Some authors have suggested a subclavian artery supply disruption sequence to explain the pathogenesis of Klippel-Feil and other vertebral anomalies.^{29,32} They hypothesize that cervical fusions result from the disruption of intersegmental vessels arising from the vertebral arteries at the time of resegmentation of the sclerotomes. Specific refinements of this hypothesis have been forwarded by Tredwell et al,³³ who reported that the fetal alcohol syndrome variant of the Klippel-Feil anomaly is always associated with a single level of congenital fusion. In contrast, other cases of Klippel-Feil have only a 20% rate of single-level fusion. They relate this finding to a specific teratogenic insult occurring between the 24th and 28th days of embryonic life.³³

Vascular occlusion may be only one of several causes of congenital vertebral anomalies. Chandraraj³⁴ described anatomical specimens in which failure of development of the zygapophysial joint appeared to cause vertebral body fusions, or block vertebrae. He suggested that in some cases, the condition was probably linked to a defect of an inductor substance (e.g., the neuraxis) that influences normal morphogenesis of the vertebral arch in the embryonic period.

The etiology of more complex vertebral anomalies, such as congenital vertebral dislocation, segmental spinal dysgenesis, and medial spinal aplasia, is currently poorly understood.^{3,16,35, 36} Dias and colleagues³⁵ have proposed that congenital vertebral dislocation arises as a result of early embryonic buckling that affects all vertebral elements in a segmental fashion between the fourth and sixth embryonic weeks.

29.5 Classification

Congenital anomalies of the spine have previously been classified according to their anatomy, pathology, or embryology.^{20,37, 38} Because a comprehensive classification scheme encompassing all types of vertebral anomalies is not available, they have traditionally been divided into disorders of vertebral formation, vertebral segmentation, or a combination of both (see box “Classification of Congenital Vertebral Anomalies” (p.365)). Many of the underlying genetic and embryologic abnormalities are only beginning to be understood. Our understanding of many disorders, including congenital vertebral dislocation, segmental spinal dysgenesis, and medial spinal aplasia, is evolving.^{16,35,36,39} This chapter relies primarily on the traditional

classification scheme and discusses the findings of the more complex disorders in a separate section.

Classification of Congenital Vertebral Anomalies

- Disorders of formation
 - Wedge vertebrae
 - Hemivertebrae
 - Caudal agenesis
 - OEIS syndrome
 - VACTERL syndrome
- Disorders of segmentation
 - Block vertebrae
 - Segmental bars
- Combination disorders
- Special disorders
 - Congenital vertebral dislocation (deformation disorder)
 - Segmental spinal dysgenesis (probable disorder of formation)
 - Medial spinal aplasia (probable disorder of formation)

Abbreviations: OEIS, omphalocele, cloacal exstrophy, imperforate anus, and spinal deformities; VACTERL, vertebral anomalies, ano-rectal malformations, cardiac malformations, tracheoesophageal fistula, renal anomalies, and limb anomalies.

Disorders of vertebral formation are regarded as failures in development of any part of the vertebral column. They may be either complete or partial and may be unilateral or bilateral. Incomplete formation of a vertebral body results in a wedge vertebra, with one side hypoplastic and with an asymmetric appearance. If one pedicle and the adjacent vertebral body are absent, a hemivertebra results. A hemivertebra can be further classified depending on whether it is fused to one or both adjacent vertebrae. An *unsegmented hemivertebra* is fused to the adjacent vertebrae above and below, a *partially segmented hemivertebra* is fused to one vertebra above or below, and a *segmented hemivertebra* is separated by a disk space from each adjacent vertebra. In the sacrococcygeal area, a more complex example of these disorders is the caudal agenesis syndrome.

Disorders of vertebral segmentation give rise to failures of vertebral separation and different degrees of intersegmental fusion (► Fig. 29.1). These disorders include block vertebrae and unilateral unsegmented bars. Block vertebrae may be the best example of a segmentation failure resulting from the failure of a somite segment to separate into cephalic and caudal halves, creating one large block with no intervening disk. A similar defect occurring on one side of the developing spinal column results in the formation of a unilateral unsegmented bar. The term *unsegmented bar* describes a bony bar that fuses the disk space and facet joints of one or more adjacent vertebral levels. The fusion may exist in the anterior spinal column, posterior spinal column, or both and may exist alone or in combination with other disorders. Vertebral growth proceeds on the segmented side only, a condition that often leads to severe scoliosis. A segmentation failure across the anterior portion of adjacent segments with normal development of the posterior portion of the vertebra leads to progressive kyphosis. Lateral segmentation anomalies are presumed to begin in the membranous and cartilaginous phases of vertebral development.¹⁷ In contrast,

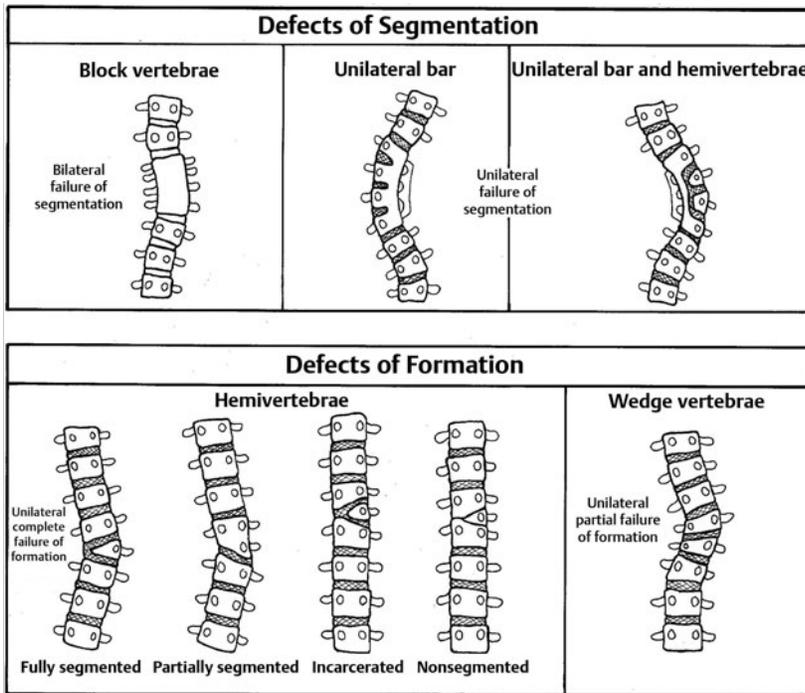

Fig. 29.1 Schematic drawings representing defects of segmentation and formation.

vertebral body segmentation anomalies are thought to arise as a result of disordered ossification.^{17,35,39}

Recent work has described a smaller, significant group of complex congenital vertebral anomalies that result in either craniocervical deformity and instability or congenital kyphoses (see box “Special Congenital Vertebral Anomalies” (p. 366)).^{35,36,39} These disorders include atlantoaxial hemivertebrae, congenital vertebral dislocation, segmental spinal dysgenesis, and medial spinal aplasia. Because it is unclear whether they can be explained by the traditional classification system, they are placed together under a separate heading. An atlantal hemiring is probably the most common cervical congenital vertebral anomaly seen by pediatric neurosurgeons.⁴⁰ Atlantal hemiring is defined as a bony discontinuity of the C1 ring in conjunction with the lateral displacement of the C1 lateral masses. It is frequently associated with occipital condyle abnormalities and absence of the transverse ligament, and it often leads to significant craniovertebral instability

Special Congenital Vertebral Anomalies

- Congenital vertebral dislocation
 - Involved vertebrae malformed
 - Superior vertebrae: elongated posterior elements with abnormally large spinal canal, bifid or incomplete laminae
 - Inferior vertebrae: misshapen, may be either smaller or larger than normal, posterior elements typically normal, spinal canal normal at this level
 - Spinal cord: intact, displaced by bony elements
- Atlantal hemiring
 - Bony discontinuity of the C1 ring in conjunction with lateral displacement of the C1 lateral masses
 - Associated with occipital condyle abnormalities and absence of the transverse ligament
 - Often causes or leads to significant craniovertebral instability

- Segmental spinal dysgenesis
 - Multilevel congenital spinal stenosis, hourglass shape of spinal canal
 - Absent pedicles, neurocentral junctions and transverse processes at involved levels
 - Stenotic posterior osseous ring encircling the spinal cord, separated from the posterior vertebral cortex by fat-filled space
 - Absent nerve roots at level of the stenosis
 - Normal vertebrae above and below the malformation
 - Spinal cord present cranial and caudal to the malformation
 - Generally normal sensorimotor function or incomplete neurologic deficits
 - High incidence of associated anomalies: tethered spinal cord, equinovarus deformities, Klippel-Feil syndrome, crossover rib, renal agenesis or duplication, situs inversus, and tetralogy of Fallot
- Medial spinal aplasia
 - Segmental or suspended agenesis of between 3 and 11 thoracic and/or lumbar vertebrae without associated lumbosacral agenesis
 - Spinal cord agenesis caudal to the malformation
 - Complete congenital paraplegia below the level of malformation
 - Severe orthopedic deformities with “Buddha-like” posture

29.6 Natural History

Because of their relatively high incidence, a good deal of information is known about the natural history of scoliotic and kyphotic curves in patients with congenital vertebral anomalies. This information, coupled with knowledge of normal and abnormal spinal growth, can be used to make decisions about the need for and timing of surgical intervention.

The growth potential associated with hemivertebrae is determined by whether the defect is segmented, partially segmented, nonsegmented, or incarcerated.⁵ A *fully segmented hemivertebra* has normal disk spaces above and below the affected level and therefore has the potential for unopposed longitudinal growth. Isolated segmented hemivertebrae in the thoracic spine produce progressive curves with a deterioration rate of 1 to 2 degrees per year. If multiple hemivertebrae exist, the rate of deterioration can be as high as 5 degrees per year. Lumbosacral hemivertebrae produce oblique spinal deformities, resulting in marked pelvic obliqueness and significant compensatory curves in the thoracolumbar spine. A *partially segmented hemivertebra* is fused with one adjacent vertebra and has less potential to produce significant deformity. A *nonsegmented hemivertebra* is fused to the vertebrae above and below and therefore has no potential for growth. In these cases, progressive deformity does not occur, and treatment is rarely required. *Incarcerated hemivertebrae* are ovoid and have narrow growth plates with little growth potential. These hemivertebrae appear to be contained by the vertebrae above and below and are rarely associated with significant deformity.

Unilateral unsegmented bars produce a unilateral growth tether and scoliosis. Isolated unilateral unsegmented bars in the thoracic spine have the potential to deteriorate at a rate of 5 degrees per year and require treatment. If bilateral failure of segmentation occurs, producing block vertebrae, then the disk spaces are symmetrically fused and therefore have little potential for producing spine deformities.

Combination deformities involving failures of both vertebral formation and segmentation are often very complex and have an increased potential for causing significant spinal deformity. The combination of a unilateral unsegmented bar with one or more contralateral hemivertebrae, for example, can lead to a rapidly deteriorating thoracolumbar scoliosis that has the potential to progress at 5 to 10 degrees per year. In many cases, these combination anomalies are fused at the time of diagnosis to prevent severe, intractable deformities in the future.

More is known about the natural history of thoracolumbar scoliosis than any other congenital vertebral anomaly. According to McMaster and Ohtsuka,⁵ 75% of congenital thoracolumbar curves will progress during growth, and 50% will require treatment. The factors associated with an unfavorable prognosis included early age at curve onset, vertebral anomaly type, and deformity location. The risk for progressive deformity was increased in the presence of block vertebrae, wedge vertebrae, hemivertebrae, two unilateral hemivertebrae, a unilateral unsegmented bar, or, most severely, a unilateral unsegmented bar associated with a contralateral hemivertebra at the same level. With each of these anomalies, the rate of deterioration was least severe in the upper thoracic region and most severe in the thoracolumbar region.

Early experience with atlantal hemirings and associated conditions (condylar aplasia or dysplasia, absent transverse ligaments, and C2 anomalies) seems to suggest that many of these patients present with craniocervical instability that may progress over time. It is common to intervene with a craniocervical fusion by the age of 4 years because the biomechanical stability of the occipitocervical complex fails over time.

29.7 Clinical Presentation and Evaluation

The clinical presentation of congenital vertebral anomalies is highly variable. Although pain is the most frequent presenting symptom among adults, incidental findings, association with other syndromes, and abnormal posture (e.g., torticollis) are the major pathways to diagnosis among children. Nevertheless, pain, weakness, sensory change, autonomic disturbance, and spine deformity may all exist alone or in combination as the presenting complaints. Pain may predominate in the midline or in a radicular fashion. Weakness and sensory changes can also be in a radicular pattern or can be part of a myelopathic syndrome involving a specific vertebral level. Autonomic disturbances, including bowel and bladder changes, may occur, with urinary incontinence often presenting early. Many patients with congenital vertebral body anomalies have symmetric fusions or blocked vertebrae and so present with no obvious spinal deformity. Indeed, if the fusion exists at one or two levels only, these individuals may not even be aware of its existence until it is revealed by radiographs taken for unrelated causes. Other individuals, however, can have much more obvious deformities that are detected at any time from birth to early adulthood.

The physical examination of a patient with suspected congenital vertebral anomaly should begin with general observations. A low-lying hairline or web neck deformity typical of Klippel-Feil syndrome or abnormalities of the ears or palate associated with Goldenhar syndrome may be noticed. Dwarfism without evidence of mental retardation may suggest achondroplasia, spondyloepiphyseal dysplasia, or some other type of skeletal dysplasia. Careful examination of the skin on the back is important to detect cutaneous stigmata of spinal dysraphism, including hairy patches, skin discoloration, dimples, lipomas, hemangiomas, and other findings. Examination of the extremities may reveal ligamentous laxity associated with Ehlers-Danlos syndrome or Larsen syndrome. Physical findings in the feet may include high arches or cavus deformity, which are common in Friedreich ataxia. The association of both foot and spine deformities strongly suggests spinal dysraphism or a generalized neuromuscular disorder. Limb length discrepancy is present if the patient is standing and the pelvis is out of the horizontal plane; this can be quantified by placing blocks of variable thickness under the short leg until the pelvis is level. The patient, dressed comfortably in an examination gown, should be standing during the examination of the spine, which should proceed in a cranial to caudal direction in a systematic fashion. In general, a “physiologic” curve is convex to the right, whereas a “pathologic” curve is convex to the left. Tenderness over the spine should be sought, as well as a determination of the range of motion. A complete neurologic examination should also be performed, with particular emphasis on the cranial nerves, sensorimotor function, and deep tendon reflexes. The patient’s gait and station may provide subtle clues for the presence of lower extremity or truncal weakness.

29.7.1 Cervical Region

Torticollis, a twisting of the neck with the head tilted toward the involved muscle and the chin rotated toward the opposite

side (“cock robin” posture), is a common physical finding among children. Torticollis usually results from unilateral contraction and fibrosis of the sternocleidomastoid muscle; however, a retrospective study of 288 patients documented 53 (18.4%) with torticollis of nonmuscular causes.⁴¹ Although the majority of these had neurologic causes, almost a third were associated with vertebral anomalies. We routinely order plain cervical spine radiographs for children who present with torticollis to exclude vertebral anomalies before the initiation of physical therapy. In selected patients (e.g., those with vertebral anomalies or with severe deformity), thin-cut computed tomographic (CT) scans with two-dimensional reconstructions are ordered to further investigate the bony anatomy. Although torticollis usually responds to physical therapy, it must be carefully monitored because it may lead to severe, progressive problems.²⁰

Although the majority of congenital vertebral anomalies in children are asymptomatic, several anomalies should be considered when children present with neck pain or torticollis. Atlantal hemirings and congenital upper cervical anomalies are relatively frequent causes of torticollis in younger children. Cervical ribs, or anomalous ribs in the cervical region that point downward, vary in size from tiny ossicles to fully formed ribs. The ribs are usually asymptomatic unless they are large enough to compress nerves or vessels. Symptoms of venous compression include pain in the ulnar distribution, neck pain, and pain along the involved part of the brachial plexus.⁴² Another uncommon anomaly of the cervical spine is an absent pedicle, which is also largely asymptomatic. In 1990, a review of 55 patients found that 31 had cervical pain, most often after trauma. The typical radiographic triad is (1) the false appearance of an enlarged neural foramen caused by the absent pedicle, (2) a dorsally displaced ipsilateral articular mass and lamina with a dysplastic and reversed facet joint, and (3) a dysplastic ipsilateral transverse process.⁴³

29.7.2 Thoracolumbar Region

Except after trauma, neurologic dysfunction associated with spinal deformity of the thoracic level is usually insidious in onset and slow in progression. Most cases are associated with idiopathic or congenital spinal deformities, particularly kyphosis. The terms *kyphosis*, *lordosis*, and *scoliosis* refer to abnormally increased convexity in the curvature of the thoracic spine (lateral view), increased anterior concavity in the curvature of the cervical and lumbar spine (lateral view), and increased lateral deviation from the normally straight vertical line of the spine (posterior view), respectively.

Scoliosis of the thoracic and lumbar spine usually presents as a painless deformity and has commonly been found in school screening programs. Juvenile idiopathic scoliosis is defined as scoliosis detected in children between 3 and 10 years of age, and adolescent idiopathic scoliosis occurs between 10 and 18 years of age. The prevalence appears to decrease with increasing curvature: 2 to 3% for a curve magnitude of more than 10 degrees, 0.3 to 0.5% for a curve of more than 20 degrees, and 0.2 to 0.3% for a curve of more than 30 degrees. Progression appears to increase with increasing curvature.²⁶

The most sensitive diagnostic screening test for thoracolumbar spinal deformity is the forward-bending test. As the patient bends forward, the presence of a rib prominence or rotation is

highly suggestive of an underlying curve and can be measured with a horizontal inclinometer. A plumb line dropped from the center of the occiput to the gluteal cleft is able to detect any lateral deviation of the trunk. Scoliotic curves should be described by their apex and location, such as a right thoracic curve, left lumbar curve, and so on. Sagittal plane deformity should also be assessed, with an evaluation for excessive kyphosis or lordosis.

29.7.3 Lumbosacral Region

Segmentation anomalies are frequently found in the lumbar and sacral spine, but they rarely produce neurologic symptoms or signs in children. Hemiblock and wedge vertebrae contribute to scoliotic and kyphotic deformities.²⁰

Caudal agenesis encompasses numerous congenital malformations of the lumbosacral spine ranging from simple anal atresia to the absence of sacral, lumbar, and possibly thoracic vertebrae to the most severe segmentation failure of the lower extremities, sirenomelia.^{6,20} Children with caudal agenesis generally show normal cognitive development but are often paraplegic and seldom have associated treatable neurologic conditions, such as spinal stenosis and tethered cord syndrome. Caudal agenesis is discussed in more detail in a subsequent section.

29.8 Diagnostic Evaluation

29.8.1 Plain Radiographs and Curve Measurement

Plain radiographs form the foundation from which congenital vertebral anomalies are detected and treated. Cervical spine radiographs—including lateral, anteroposterior, and odontoid views—are mandatory when clinical evidence of cervical abnormalities is present. Careful interpretation, however, is paramount because normal vertebral growth and ossification may show variable patterns. In most patients with congenital vertebral anomalies of the cervical spine, dynamic flexion and extension studies should be performed to determine whether instability is present and to assess whether there is any change in the spinal canal width. If thoracolumbar scoliosis is suspected, then upright lateral and anteroposterior plain radiographs of the entire spine should be obtained for initial curve assessment. The Cobb method is recommended by the Scoliosis Research Society to measure the degree of spinal deformity. It is applicable to both idiopathic and congenital curves. To use the Cobb method, the examiner chooses the most tilted vertebrae above and below the apex of the curve. Lines are then drawn extending from the superior end plate of the top vertebra and the inferior end plate of the bottom vertebra. The angle formed when intersecting lines are drawn perpendicular to the above lines is the Cobb angle. Imaging the entire spine on a single radiograph allows an assessment of the magnitude of the curve, the pattern of vertebral anomalies, and the overall balance in sagittal and coronal planes. Equally important, it also allows an assessment of progressive decompensation and spinal balance.

29.8.2 Special Imaging

CT provides detailed information regarding the bony anatomy of congenital vertebral anomalies and is invaluable in the

treatment-planning phase of these disorders. Thin-cut (1 mm) axial CT scans with multiplanar computer reformatting in the sagittal and coronal planes (1 mm) give further insight into the anatomy of the anomaly, especially those in the cervical region. In addition, two-dimensional parasagittal reconstruction of the atlantoaxial region is critical when the use of C1–2 instrumentation is being contemplated for the treatment of instability at the craniocervical junction.^{44–46} With the advent of magnetic resonance (MR) imaging, the use of CT myelography for the evaluation of spinal cord anatomy has decreased precipitously. There are cases, however, where CT myelography may be preferable to MR imaging, such as when spinal instrumentation overlies the area of interest and produces significant MR imaging artifact.

MR imaging is the study of choice for evaluating spinal cord pathology. Congenital anomalies and acquired defects of the spinal cord can be identified at all spinal levels. Because of the inherent difficulty of detecting bony abnormalities with MR imaging, however, more than one imaging modality is often required. Plain radiographs, CT, and MR imaging all may be necessary to completely understand the anatomy of a given lesion. Because multiple spinal anomalies are commonly present in the individual patient, it is important to image the entire spine if any malformation is suspected.

In infants, ultrasound can be useful initially because monitoring devices do not need to be removed, transport is often not required, and patients can be closely observed during the examination. Furthermore, ionizing radiation is not involved, sedation is not required, and most institutions have the requisite equipment.⁴⁷ Among other things, ultrasound can provide information about posterior cystic lesions, Chiari malformation, syringomyelia, diastematomyelia, and the position of the conus.⁴⁸

29.9 Associated Anomalies

The physical proximity of the branchial arches, genitourinary system, viscera, and other tissues to the spinal column during development permits a localized teratogenic event to have an effect on multiple organ systems. The branchial arches arise from the intermediate mesoderm adjacent to the cervicothoracic somites. Thus, derangement of the somites or developing vertebrae can be associated with malformations of the structures that arise from the branchial arches. These structures include the outer ear, ossicles, semicircular canals, mandible, and parts of the maxilla and hyoid bone.^{49,50} Patients with Apert, Crouzon, or Treacher Collins syndrome, for example, tend to have craniocervical abnormalities or blocked cervical vertebrae and associated complex craniofacial anomalies. Those with Goldenhar syndrome often have cervicothoracic scoliosis associated with a hemifacial microsomia, with severe ear deformities frequently noted. The unilateral hypoplasia or absence of the ear in this syndrome is associated with mandibular hypoplasia, macrostomia, an ocular dermoid, and fused vertebrae or hemivertebrae, usually in the lower cervical and upper thoracic levels.⁵⁰

The pronephros also originates at the level of the lower cervical spine, and teratogenic factors at those levels can be associated with abnormal development of the genitourinary

system.⁵¹ Genitourinary anomalies, including unilateral kidney, ureteral obstruction, and duplication of the kidney, may occur in up to 25% of patients with congenital scoliosis.⁵²

Because of the close proximity of the developing spinal cord to the osseous structures in the spine, malformations of the central nervous system often coexist with congenital vertebral anomalies.⁵³ For example, Bradford and colleagues⁵⁴ found a 38% incidence of intraspinal anomalies in 42 patients with congenital scoliosis. There was also a 52% incidence of spinal cord abnormalities, with unilateral unsegmented bars and contralateral hemivertebrae. Other studies have shown that split-cord malformations are present in 5 to 20% of patients with congenital scoliosis.⁵⁵

29.10 Congenital Vertebral Anomaly Syndromes

29.10.1 Klippel-Feil Syndrome

Klippel-Feil syndrome is a relatively rare entity that is classically described as the clinical and radiographic triad of short neck, low posterior hairline, and cervical vertebral segmentation abnormalities. All three components of the triad occur in only about 50% of patients with the syndrome, leading to the alternative description of a Klippel-Feil “variant,” which encompasses a larger number of patients. Although the true incidence of Klippel-Feil syndrome or variant in the general population is unknown, it is estimated in reports to be 1 in 42,000 live births, or somewhere between 0.02 and 0.7% of the population.^{56–59}

Klippel-Feil syndrome is usually diagnosed in children after incidental radiographic studies. Gross spinal deformities, torticollis, scoliosis, or acute cervical symptoms occurring immediately after a relatively mild injury, however, may indicate the syndrome before imaging is obtained. In a minority of cases, Klippel-Feil syndrome presents as chronic cervical symptoms lasting months: progressive neck and upper extremity pain, paresthesia, or weakness; ataxia; vertigo; headaches; and vision problems.

Klippel-Feil syndrome is most often seen as a sporadic disorder, although autosomal-dominant and autosomal-recessive cases have been reported. Mutations in the *GDF6* and *GDF3* genes, both encoding bone and cartilage regulatory proteins, have been identified to cause the disease. Several different hypotheses have been proposed over the years to explain its origin and include primary vascular disruption, global fetal insult, primary neural tube abnormality, genetic predisposition, and failure of facet joint segmentation (see the previous section on etiology).^{29,32,34,60}

Abnormalities in virtually every organ system have been associated with Klippel-Feil syndrome. These include Chiari 1 malformation with or without syringohydromyelia and developmental anomalies of the head such as high-arch palate, lid ptosis, cleft palate, facial nerve palsies, Duane contracture of the lateral rectus muscle, and mixed-type hearing loss.^{61,62} Between 30 and 60% of patients with Klippel-Feil syndrome have genitourinary abnormalities, including unilateral kidney, malrotation of a normal kidney, ectopic kidney, horseshoe kidney, and renal pelvic and ureteral duplication, or genital anomalies.^{61,63,64} Unilateral renal agenesis, the most common anomaly among patients with Klippel-Feil syndrome, is 400 times more

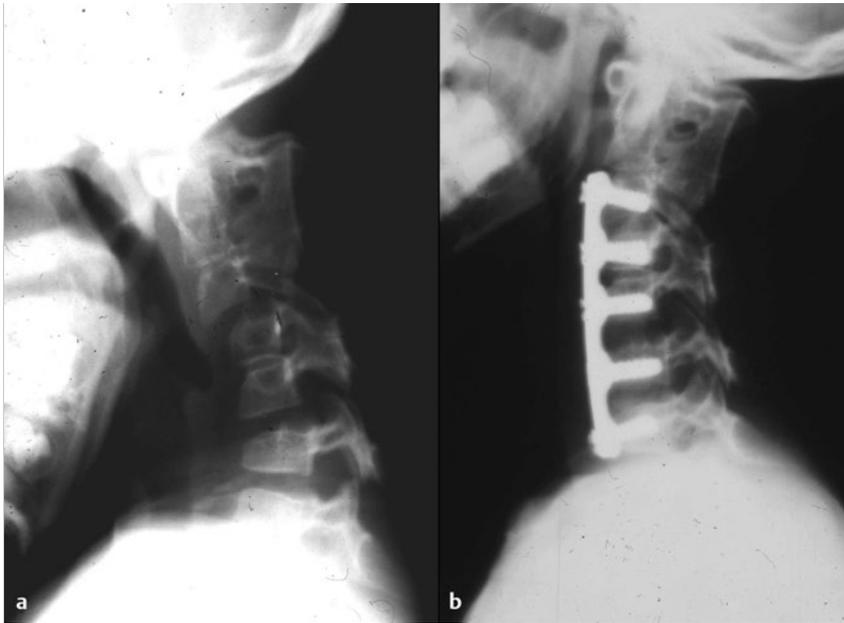

Fig. 29.2 A 9-year-old girl presented with Klippel-Feil syndrome. (a) Plain lateral cervical spine radiograph in flexion reveals significant subluxation at the C4–5 and C6–7 levels. (b) Postoperative lateral radiograph demonstrates multilevel anterior cervical discectomy and fusion with plating. The patient went on to have a successful fusion.

common in these patients than in the unaffected population. Among cardiovascular anomalies (which affect 4 to 5% of patients with Klippel-Feil syndrome), the most commonly reported are coarctation of the aorta, patent ductus arteriosus, mitral valve disease, and ventricular septal defects. Pulmonary anomalies include failure of lobe development, rib fusion, and ectopic lung secondary to a deformed trunk and rib cage. Syndactyly, elevation of the scapula (Sprengel deformity), and pterygium colli (webbing of the skin on the lateral side of the neck) have been reported.^{61,65} Hearing loss is common in patients with Klippel-Feil syndrome, occurring in up to 30%.⁶⁶ Accessory cervical ribs are found in 15% of patients with Klippel-Feil syndrome, whereas only 1% of individuals in the general population are similarly affected.⁶⁵

The Klippel-Feil syndrome involves segmentation anomalies of the spine, including fused vertebrae, hemivertebrae, occipitalization of the atlas, scoliosis, and spina bifida occulta (► Fig. 29.2). This places the cervical spinal cord at risk primarily because of the resulting biomechanical abnormalities. A common abnormality is congenital fusion of the second and third cervical vertebrae in conjunction with assimilation of the atlas.⁶⁷ Although this combination has been reported to result in atlantoaxial subluxation approximately 50% of the time,⁶⁸ our institutional experience suggests a much lower rate of instability (about 5%). Furthermore, congenital fusions over several spinal segments reduce the ability of the cervical spine to compensate for excessive forces in flexion, extension, rotation, and lateral bending, and stresses that might be tolerated by a patient who has a normal neck are not safe for one who has a cervical spine with limited mobility. Forces applied to the neck develop moments at each motion segment, and if only one or two motion segments exist where there should be eight, the force may exceed the strength of the restraining ligaments, leading to dislocation and injury to the spinal cord. In reported cases of patients with Klippel-Feil syndrome and spinal cord injury, the trauma is often minor or indirect, with the dislocation frequently self-reducing.^{69,70} Congenital spinal stenosis may

also be present in patients with Klippel-Feil syndrome, increasing the risk that even minor stress applied to the cervical spine can lead to neurologic injury.^{71,72} Anesthetic considerations for these patients are significant because children with Klippel-Feil syndrome are at high risk for spinal cord injury during laryngoscopy, intubation, and positioning.^{73,74}

After the original case description in 1912 by Klippel and Feil, Feil⁷⁵ developed a classification scheme in 1919 based on the location and extent of the vertebral anomaly. Type 1 lesions consist of massive fusion of the cervical vertebrae, sometimes extending to the upper thoracic spine, causing severe disability and an abnormal appearance. Type 2 lesions consist of only one or two fused vertebral segments and generally cause no symptoms in the first decades of life. Type 3 lesions are type 1 or type 2 lesions associated with distant anomalies of the thoracic or lumbar spine. In a study of 57 patients with Klippel-Feil syndrome, 40% were found to have type 1 lesions, 47% to have type 2 lesions, and 13% to have type 3 lesions.⁷⁶

The natural history of Klippel-Feil syndrome is incompletely understood. One of the most significant unanswered questions remains the fate of normal cervical levels adjacent to the naturally fused vertebral segments. In an attempt to answer this question, Theiss and colleagues⁷⁷ reported the long-term follow-up (over 10 years) of 32 patients with Klippel-Feil syndrome and congenital scoliosis. They discovered that only a small number of patients with Klippel-Feil syndrome and congenital scoliosis developed cervical symptoms, and they could not identify a fusion pattern that placed a patient at greater risk for such symptoms. In addition, the only factors that led to cervical symptoms were fusion at the cervicothoracic junction and congenital cervical stenosis. Nagib and colleagues^{73,78} also reviewed a group of patients with Klippel-Feil syndrome in an effort to identify those who were at higher risk for neurologic injury. The small number of patients, however, precluded meaningful recommendations. Further studies are needed to clarify the issue of when surgical fusion is necessary if an unstable, or potentially unstable, cervical segment is identified.

Several reports illustrate the importance of early, systematic studies and long-term follow-up.^{79,80} We routinely order cervical spine radiographs and perform neurologic examinations on a yearly basis for these patients.

29.10.2 Atlantal Hemiring Complex

Recent work has described a complex congenital vertebral anomaly of the craniocervical junction termed *atlantal hemirings*.⁴⁰ It is characterized by abnormal formation of the load-bearing structures of the craniocervical complex and includes lateral displacement of the lateral masses of the atlas, frequent absence of the transverse ligament, and variable amounts of dysplasia or aplasia of the occipital condyles and C2 lateral masses. It can be associated with Klippel-Feil syndrome. Patients typically present at an early age, sometimes before 1 year, with either torticollis or evidence of a cervical spine abnormality on routine radiographs such as chest radiographs. It is common for initial dynamic cervical spine radiographs to show evidence of significant craniocervical instability (► Fig. 29.3), and instability often increases as children age because of the greater stresses placed on the atlanto-occipital complex in older children lacking several major supporting craniocervical structures. Older patients (older than 3 or 4 years of age) who demonstrate significant instability may undergo fusion procedures shortly after presentation, whereas younger patients may be managed with a hard cervical collar and monitored with serial dynamic cervical spine radiographs until it is appropriate to proceed with surgical stabilization.

29.10.3 Osteochondrodysplasias, Collagenopathies, and Mucopolysaccharidoses

These disorders comprise a large number of syndromes that are associated with abnormal bony structure or metabolism. Common syndromes causing vertebral dysgenesis are listed in ► Table 29.1. They are mentioned in this chapter because abnormal

bony architecture or weakness inherent in the bone may lead to the collapse of vertebral segments or overt spinal instability. They must be managed according to the principles that guide the care of all children with vertebral anomalies. A short discussion of a few common disorders is appropriate here.

Osteochondrodysplasias

Osteochondrodysplasias are diseases that result in abnormal formation of either bone or cartilage. Achondroplasia is the most prevalent form of chondrodysplasia and is extensively covered in the following chapter. Other osteochondrodysplasias include Langer-Giedion syndrome, chondrodysplasia punctata, and diastrophic dwarfism (► Fig. 29.4).

Collagenopathies

Collagenopathies are a group of disorders affecting connective tissue. They are caused by mutations in the *COL11A1*, *COL11A2*, and *COL2A1* genes. They include disorders such as spondyloepiphyseal dysplasia (SED) congenita and Kniest syndrome. SED is characterized by congenital dwarfism, with a short trunk, scoliosis, and epiphyseal dysplasia in the long bones and vertebral bodies.^{81–84} In addition to flat vertebral bodies and other congenital vertebral anomalies, a hypoplastic dens or os odontoidum is present in nearly all patients with SED, leading to atlantoaxial instability in 35 to 60% of patients.⁸⁵ Because patients with SED and spinal instability have had poor neurologic outcomes after even minor traumatic injuries, most authors advocate prophylactic surgical fusion regardless of spinal cord symptoms in the setting of instability.^{85–87} In our experience, most patients with SED have required surgical fusion. Additional challenges when surgical intervention is being considered for these patients include their small size for age, reduced pulmonary function, and often extreme spinal deformity.

Mucopolysaccharidoses

Mucopolysaccharidoses are a group of metabolic disorders caused by the absence or malfunction of lysosomal enzymes needed to break down glycosaminoglycans. These include Morquio, Hunter, and Hurler syndromes. A hypoplastic or aplastic dens is common in Morquio syndrome, with varying degrees of atlantoaxial subluxation present. Atlantoaxial fusion is often necessary to manage the instability.

29.10.4 Larsen Syndrome

Larsen syndrome is a complex syndrome with genetic heterogeneity and both autosomal-dominant and autosomal-recessive patterns of inheritance.^{88,89} It is caused by a mutation in the *FLNB* (filamen B) gene. Often categorized under the diagnosis of

arthrogryposis multiplex, Larsen syndrome is characterized by multiple congenital joint dislocations, a flattened facies, club-foot deformities, and cleft palate.⁹⁰ Although not emphasized in early descriptions of the syndrome, abnormalities of the cervical spine—specifically kyphosis, coronal clefts of the vertebrae, subluxation of the vertebrae, and atlantoaxial instability—can be the most serious manifestations of the disease.^{91–96} There is little information in the literature regarding treatment outcomes in these patients. Most authors advocate operative stabilization to reverse or prevent neurologic deficits. In patients with cervical kyphosis, posterior cervical fusion with instrumentation has been reported to provide stability and the opportunity for gradual correction of the deformity by continued anterior growth⁹² (► Fig. 29.5). If a severe kyphotic deformity is present, however, combined anterior and posterior stabilization procedures may be indicated.

29.10.5 Segmental Spinal Dysgenesis

Segmental spinal dysgenesis is a malformation resulting from an embryonic segmental malformation or focal injury to the developing spine in utero. Affected children are identified at birth by a sharply angled kyphotic deformity (thoracolumbar junction), anomalies of the lower extremities (usually equinovarus deformities of the feet and flexion contractures of the hips and knees), hyperreflexia of the lower extremities, and bladder dysfunction (usually manifesting as a low-pressure, dribbling urine stream).³⁷ There is marked focal hypoplasia of the vertebral column, typically at the thoracolumbar junction. Imaging studies reveal a kyphotic deformity with hypoplasia or absence of one or more vertebral bodies (► Fig. 29.6). Below the segmented agenesis, the bony spinal canal, thecal sac, and spinal cord resume a normal appearance. Evaluation of the entire spinal column is essential because affected patients may have associated lipomas, dermal sinuses, or syringomyelia. Surgery to decompress the bony narrowing at the site of dysgenesis can lead to an

improved neurologic outcome in some cases.³⁶ Early anterior and posterior arthrodesis is recommended for patients who have segmental spinal dysgenesis because the progressive kyphosis that inevitably develops often results in neurologic deficits.^{16,36}

29.10.6 Caudal Agenesis

The syndrome of caudal agenesis comprises a spectrum of anomalies, including sirenomelia (fusion of the lower extremities),

absence of the most caudal vertebral bodies and spinal cord, anal atresia, malformed external genitalia, exstrophy of the bladder, renal aplasia or ectopia, and pulmonary hypoplasia with Potter facies.³⁷ The vertebral malformations range in severity from agenesis of the coccyx to complete absence of the sacral, lumbar, and possibly even lower thoracic vertebrae.⁶

For practical purposes, the terms *caudal agenesis*, *caudal regression*, and *sacral agenesis* are synonymous. The reported incidence of caudal agenesis is approximately 1 in 7,500 births, although the wide clinical spectrum of malformations seen and the variability in diagnostic criteria preclude a truly accurate estimate.²⁴ Multiple classification schemes have been proposed over the years to describe caudal agenesis,^{2,97,98} but the most complete and useful system is likely the one proposed by Pang.⁶ The syndrome seems to result from disturbances of the caudal mesoderm, including the caudal cell mass and cloaca, before the fourth week of gestation.²⁴ The insult presumably impairs the normal migrations of neurons, paraxial mesodermal cells (somites that form the vertebral bodies), and lateral mesoderm cells that form the lower digestive tract.⁹⁹ Although the specific insult is unknown, there is a strong association with maternal diabetes^{100–102} and a softer association with industrial areas.²⁴

Because the urogenital and gastrointestinal systems are closely related to the vertebral column during development, caudal agenesis is often found in association with multisystem malformation syndromes. The most important of these are OEIS deformities (omphalocele, cloacal exstrophy, imperforate anus, and spinal deformities), which occur in approximately 10% of cases, and VACTERL anomalies (vertebral anomalies, anorectal malformations, cardiac malformations, tracheoesophageal fistula, renal anomalies, and limb anomalies), which occur in another 10% of cases.⁶ In nonsyndromic caudal agenesis, vertebral, urogenital, and anorectal anomalies occur together in a rather consistent triad. Other anomalies that may occur alone or in

combination with sacral agenesis include Hirschsprung disease, anal stenosis, renal anomalies, ambiguous genitalia, salpingoovaginal anomalies, and fistulas.

The presence of progressive neurologic deficits in patients with sacral agenesis is well-known and has been emphasized by Pang and Hoffman.^{6,7} Spinal cord tethering may be associated with a thick filum terminale (65%), terminal myelocystocele (15%), terminal hydromyelia (10%), or lipomyelomeningocele (10%). It is recommended that all tethering spinal cord lesions associated with caudal agenesis be released when progressive neurologic deterioration occurs. The role for prophylactic tethered cord release in this setting, however, is less clear.

29.10.7 MURCS Association

A distinctive association of müllerian duct aplasia, renal agenesis or aplasia, and cervical and thoracic spine dysplasia is described as the MURCS association.¹⁰³ Most patients are female. It is theorized that the association occurs because of the intimate spatial relationship at 4 weeks of development (blastoma phase) between the lower cervical and upper thoracic spine somites and the pronephric duct (which later induces müllerian duct development). A teratogen would alter all three of these structures and their subsequent development. Duncan⁵¹ reported that among patients with MURCS association, 80% have involvement of two to four vertebrae, 88% have renal agenesis or ectopia, and 96% have uterine hypoplasia or aplasia. Although there are reports of families with siblings who have MURCS, most cases seem to be sporadic.

29.11 Treatment Options

A discussion concerning all the possible treatment options and techniques for congenital vertebral disorders from the subaxial spine to the coccyx is well beyond the scope of this chapter. Furthermore, it is difficult to compare various surgical strategies with any degree of statistical confidence because surgery is not commonly necessary for children with congenital vertebral anomalies. It is appropriate to stress certain treatment principles that guide the management of these complex and varied disorders. In many cases, both neurosurgeons and orthopedic spine specialists must work together to treat the condition in a multidisciplinary fashion.

With the exception of juvenile idiopathic scoliosis, most pediatric experience comes from children who have anomalies such as Klippel-Feil syndrome and achondroplasia and from children whose anomaly was discovered incidental to trauma. Conservative treatment is always the first strategy when there is no immediate threat of permanent neurologic injury because therapy, exercise, and bracing can provide significant benefit for many children with congenital anomalies of the spine. It is important to determine whether clinical instability exists. Clinical instability is classically defined as loss of the ability of the spine under physiologic loads to maintain its pattern of displacement so that there is no initial or additional neurologic deficit, no major deformity, and no incapacitating pain.¹⁰⁴ Indications for surgery include the following: (1) reduction and/or stabilization of significant spinal deformity, (2) treatment of instability, (3) protection of the neural elements, and (4) relief of medically intractable pain, although this problem is rare in children.^{27,105}

29.11.1 Cervical Lesions

There are no published guidelines regarding the point at which cervical deformities or instability must be corrected with surgery. Minor cervical deformities or intervertebral motion that is greater than normal may be well tolerated by patients over many years. In cases of congenital or acquired cervical kyphosis or gross craniocervical instability, on the other hand, surgical correction may be required. Operative strategies to protect the neural elements in congenital vertebral anomalies usually involve bony decompression and/or fusion to improve or maintain neurologic function and axial alignment. It has been demonstrated that halo bracing or other cervicothoracic orthoses are often not successful in the face of a progressive craniocervical deformity.⁶⁵ The rate of curve progression, neurologic symptoms, and pain are all important factors in the decision to proceed with surgery. The decision for intervention must be made with the entire clinical picture in mind.

In the past, most patients underwent Gardner-Wells tongs traction before surgical correction of their deformity. Recently, however, improvements in spinal instrumentation have led to the ability to correct the vast majority of craniocervical deformities intraoperatively with rigid screw fixation techniques (► Fig. 29.7), which include both posterior and anterior approaches to the craniocervical area. Considerable experience has been accumulated with these techniques in the last decade in pediatric patients with a high degree of success. When an operative procedure is being, it is important to keep in mind that the need for external halo fixation postoperatively is low, as is the need for graft extenders such as bone morphogenetic protein-2 (BMP-2). In addition, successful allograft fusions have become more common and can be considered. Of course, the most critical factor for success is always the surgeon's training and technique.^{44,68,106}

Patients who have skeletal dysplasia often present with instability of the upper cervical spine. The presence of significant instability with atlantoaxial translation of more than 5 mm or cord compression in the upper cervical spine usually requires fusion.²⁷ If the C1 posterior arch is missing or bifid, as commonly occurs in patients with SED, fusion may need to extend to the occiput. Otherwise, only the two levels comprising the unstable segment need to be fused. Treatment options include posterior bone and wire fusion with external halo orthosis or posterior fusion with instrumentation. As mentioned before, many of the available instrumentation procedures eliminate the need for an external halo orthosis, which is a significant factor when a potential surgical procedure is being considered.⁴⁴⁻⁴⁶

Subaxial cervical instability secondary to congenital vertebral anomalies is relatively common and is most often seen in relation to Klippel-Feil syndrome. In that circumstance, an unstable vertebral level is commonly next to block vertebrae. Although either an anterior or a posterior surgical approach can be used to achieve fusion, we have had excellent results in which an anterior approach was used with an interbody graft and instrumentation (► Fig. 29.8). An anterior approach is also required when congenital swan neck deformities are treated. In this case, the apex of the kyphosis can be resected to achieve satisfactory neural decompression and facilitate curve correction and fusion; however, a posterior fusion with instrumentation must often be added to the anterior procedure to achieve complete reduction and stabilization (► Fig. 29.9).

Part of the general treatment strategies for cervical congenital vertebral anomalies often involves discussions regarding activity restriction for the patient. Although there is no statistical evidence to suggest that uncomplicated stenosis of the cervical canal in a person with a stable spine predisposes the person to a permanent neurologic injury, experience suggests that children with fused cervical vertebrae, with or without craniocervical anomalies, are at risk for injury to the cervical cord from relatively minor trauma.⁷⁹ In general, recommendations have been advanced to restrict participation in collision activities (including football, hockey, wrestling, and other contact sports) in people who have a documented episode of cervical cord neurapraxia associated with unstable ligaments, disk disease with cord compression, significant degenerative changes, radiographic evidence of a cord defect or swelling, neurologic symptoms lasting more than 36 hours, and more than one recurrence.¹⁰⁷

29.11.2 Thoracolumbar Lesions

The goals for the treatment of thoracolumbar congenital vertebral anomalies are similar to those for the treatment of cervical lesions. The ultimate goal is to obtain a balanced spine that is as close to a complete correction as possible at the completion of growth. Because congenital scoliosis is a complex growth disturbance, treatment decisions and surgical timing may be difficult to determine. Each treatment strategy must be individualized based on the age of the patient at presentation, the type of vertebral anomaly, and the expected curve progression with growth. The treatment of adolescent or juvenile idiopathic scoliosis is not covered here.

The decision to surgically intervene in a congenital thoracolumbar vertebral anomaly requires regular assessment of the patient's growth and spinal curvature. This assessment can be achieved with serial radiographs. Yearly comparison of the radiographs is essential because growth within congenital vertebral anomalies may be unpredictable. Fundamentally, spinal growth occurs in areas of active end plates. Therefore, to control abnormal spinal curvature, sometimes the only option may be to retard a growing segment to maintain spinal balance. From an overall management point of view, it is often advisable to prevent a severe deformity rather than wait to correct one. It is often preferable to have a short, straight spine rather than wait for the completion of growth and attempt to correct a severe, decompensated curve later. A unilateral unsegmented bar with contralateral hemivertebrae, for example, is so predictably malignant that early anterior and posterior fusion is indicated upon recognition (► Fig. 29.10). In addition, experience with congenital vertebral dislocations seems to suggest that aggressive management with anterior and posterior approaches results in the highest rate of success.^{35,36,39} On the other hand, many simple curve patterns, such as an isolated hemivertebra, remain well compensated and do not require intervention (► Fig. 29.11).

Thoracolumbar scoliosis due to congenital vertebral anomalies may be managed by observation, bracing, or surgery. Observation is appropriate for small curves, balanced curves at skeletal maturity, and curves at low risk for further progression, such as those associated with block vertebrae. Infantile idiopathic scoliosis, for example, may resolve if significant trunk rotation is not present.²⁷ This can be determined by measuring an angle

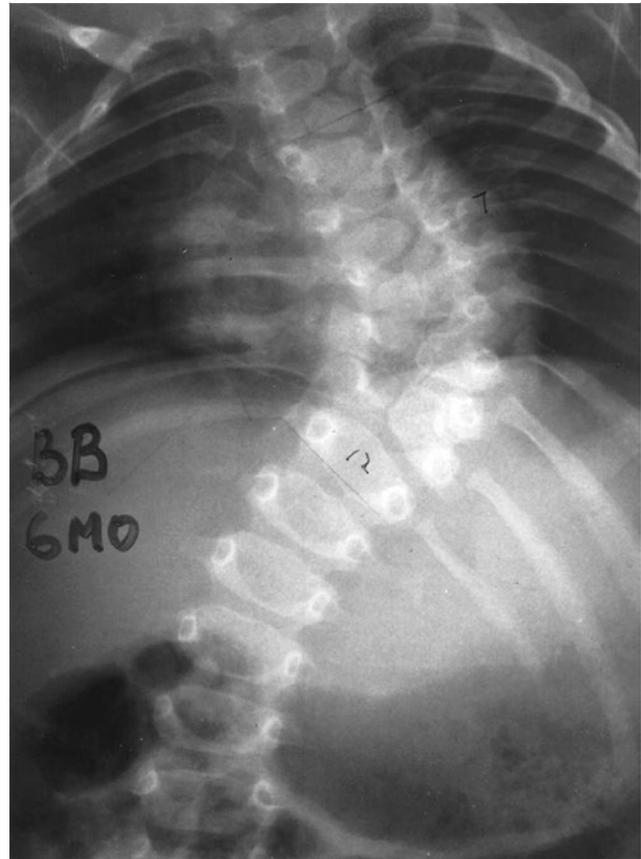

Fig. 29.10 Plain anteroposterior thoracic spine film in a 6-month-old child with unilateral failure of segmentation in association with multiple contralateral hemivertebrae.

between the ribs of less than 20 degrees at the apex of the deformity. Approximately 25% of children with congenital scoliosis may be managed with observation alone.¹⁰⁵ Neither exercise nor electric stimulation has any proven value.²⁷

Bracing for congenital scoliosis is appropriate only in very specific circumstances. In the presence of a severe growth imbalance, a brace will never control curve progression. The principal value of bracing is to control the secondary spinal curvature resulting from the primary congenital curve. Bracing can also be of value after surgical correction in maintaining spinal balance during the process of fusion maturation.

Accepted techniques for the surgical management of congenital thoracolumbar scoliosis are posterior fusion without instrumentation,^{108,109} posterior fusion with instrumentation,^{109,110} anterior fusion with instrumentation,¹¹¹⁻¹¹⁴ and convex anterior and posterior epiphyseodesis.¹¹⁵⁻¹¹⁷ Some authors have recommended posterior fusion in situ (without attempting correction) for any curve with documented progression of more than 10 degrees.²⁷ The advantages of posterior fusion alone are its relative simplicity, neurologic safety, short hospitalization, low blood loss, and well-established track record.¹¹⁸ The disadvantages include minimal ability to correct an established curve, the need for a postoperative orthosis, and the potential for bending of the fusion mass with growth. Furthermore, young patients undergoing posterior fusion for hemivertebrae may develop the so-called crankshaft phenomenon or progressive lordosis.²⁷

Fig. 29.11 Plain anteroposterior thoracic spine radiograph in an 18-month-old child with a balanced pattern of multiple hemivertebrae due to a hemimetameric shift. This pattern of multiple segmented hemivertebrae allows good sagittal balance to be maintained.

Posterior instrumentation may be added to posterior fusion when some degree of correction is desirable in addition to arresting the progression of the curve. The advantages of adding instrumentation include a gain of some degree of correction, a reduction in the pseudarthrosis rate, and less dependence on corrective postoperative bracing. The disadvantages include a higher risk for the neurologic complications associated with instrumentation and spinal distraction during correction.^{108,110,119,120} These risks can be reduced by obtaining MR images preoperatively and using intraoperative spinal cord monitoring or a wake-up test. It is recommended that coexisting intraspinal anomalies requiring surgical correction (e.g., tethered cord) be managed first, before the congenital scoliosis is corrected.

More recently, anterior approaches with instrumentation have been used to achieve correction and fusion in some patients.¹¹¹⁻¹¹⁴ Advantages of this approach include correction and rebalance of the trunk through a shorter fusion segment, thereby preserving motion segments.¹¹¹⁻¹¹³ Disadvantages include a higher rate of implant breakage¹¹¹ and complications inherent to an anterior approach to the thoracolumbar spine, including transient sympathetic disturbances.¹¹²

Convex growth arrest of the spine through an anterior and posterior epiphysiodesis is a management alternative in younger children with a small amount of progressive scoliosis (► Fig. 29.12).^{109,110} Curve progression often results from unbalanced growth of the convex side of the anomaly. It follows that arresting this convex growth will stop further progression of the curve. If the concave side has a potential for growth, then some correction is expected from that side as well. An anterior hemiepiphysiodesis is another option for some patients, with its major advantage being that the spine may continue to grow, allowing gradual correction of the curve. The thoracic cavity and spine may be expected to have a better growth potential with this procedure than with an early circumferential fusion. The most common disadvantage is that the procedure may be only partially successful, slowing but not halting curve progression.

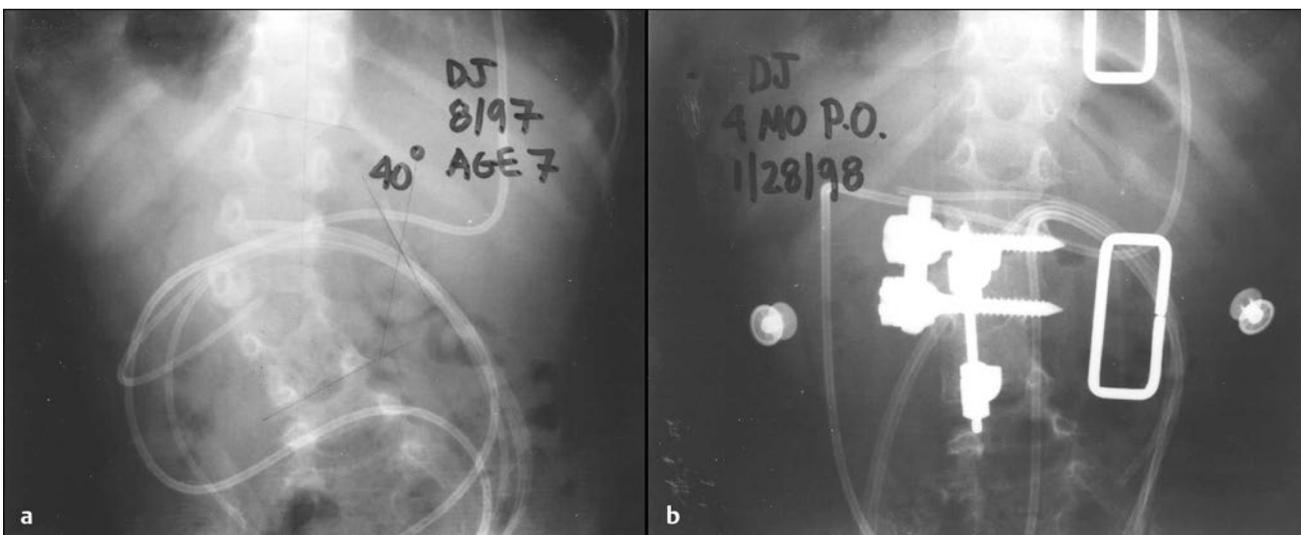

Fig. 29.12 (a) Plain anteroposterior film of the thoracolumbar spine in a 7-year-old boy with an isolated hemivertebra at L3 and hydrocephalus since birth. He developed a gradual loss of coronal balance with a progressive curve. (b) Thoracolumbar radiograph 4 months after an anteroposterior hemivertebrectomy shows that his coronal balance was restored.

Furthermore, the spine must be protected in a brace or cast while it is growing to avoid loss of fixation, which may lead to gradual rib deformity and a disproportionately small thorax.¹²¹

Excision of a hemivertebra may also be used to provide curve correction in certain cases.^{122,123} The principal indication of this procedure is the presence of a hemivertebra at the lumbosacral junction producing an oblique takeoff of the spine from the pelvis. Its main advantage is that immediate deformity correction and the restoration of spinal balance are achieved while fusion of a limited number of spinal segments is required. The disadvantages include the complexity of the procedure and an increased risk for neurologic injury. Significant amounts of correction are possible, and correction does not depend on unpredictable growth on the concave side of the curve.

Spondylolysis (alternatively isthmic spondylolisthesis), a failure of the neural arch manifesting as a defect in the pars interarticularis, is a congenital anomaly found throughout the spine that is often associated with other abnormalities, including spina bifida and dysplasia of the posterior processes.¹²⁴ It appears to be well tolerated, and it is most often medically managed in the adult. Nonoperative management usually suffices, but surgical intervention is occasionally required for those who are not successfully treated with reduction of activity and bracing. Recently, direct repair of the pars in the lumbar spine has been demonstrated to be a safe and effective modality to treat selected groups of patients with spondylolysis.¹²⁵ The advantage of direct pars repair over intertransverse fusion with or without segmental instrumentation is preservation of the anatomical integrity and motion of the affected segment. It is important, however, to distinguish relatively benign spondylolysis from spondylolisthesis with other, unstable causes, such as trauma.¹²⁶

29.12 Conclusion

Congenital vertebral anomalies are a dynamic, complex group of lesions occurring in the maturing spine. Intimate knowledge of their anatomy, biomechanics, and natural history is required to manage them effectively. A team approach is helpful in achieving management goals. Further effort is needed to better understand these complex issues.

Pearls

- Congenital vertebral anomalies are quite common. Many times, a combination of plain X-rays, CT, and MR imaging is necessary to establish a precise diagnosis.
- Once a diagnosis is made, important issues to address are the risk for neurologic injury, the risk for future deformity, and the presence or absence of spinal instability. In general, indications for surgery include the presence of a neurologic deficit or spinal instability or the prevention of future deformity.
- Modern surgical stabilization techniques, including rigid instrumentation, have allowed pediatric spine surgeons to manage more complex procedures with better outcomes.
- Much work remains to be done in this arena, including establishing the natural history of most disorders, the use of spine biologics in surgery, and the long-term outlook for children living with a spinal arthrodesis.
